(Received October 24, 2014 and accepted November 14, 2014)

Extreme climate phenomena are occurring around the world caused by global climate change, and Korea is no exception. Heavy rains continue to occur in Korea, which exceed the previous highest rainfall records. In particular, as flash floods generate heavy rainfall on the mountains over a relatively a short period of time, the likelihood of landslides increases. Therefore, it is necessary to scientifically analyze landslide risk areas to minimize damage in the event of a landslide, and to collect and analyze a variety of spatial information. This study constructs a spatial information database using GIS and integrating geography, hydrology, geology, and forestry, which is required for a complete analysis of landslide risk areas. We also carried out a case study of Injegun, Gangwondo, which suffered from serious landslides and flash floods in 2006 after Typhoon Ewinar, by overlaying site monitoring data with airborne images.

Furthermore, this study evaluates slope stability of the affected areas using SINMAP (Stability Index Mapping), analyzes spatial data that have high correlation with selected landslide areas using Likelihood Ratio, and prepares landslide prediction of the mountainous areas that are vulnerable to disasters.

**Key words:** Landslide, GIS, SINMAP, Likelihood Ratio

### INTRODUCTION

Up to 64% of the Korean territory is covered by forest. There are many steep slope areas with 30–60° tilt angles, and 90% of the mountainous areas consist of granite and metamorphic rocks. Many landslides occur in Korea each year due to climatic, geographical, geological, and human-induced reasons. In Gangwondo, 81% of the area consists of mountains and most of the mountain sides have steep slopes. As a result, this area suffers annually from many landslides. For example, heavy rains and Typhoon Ewinar in July, 2006 caused many landslides throughout Gangwondo. In Injegun (the mountainous area accounting for 90% of the total area), heavy rains, which fell over a short period of time, caused serious damage to small- and medium-sized streams that had narrow drainage areas. During this flash flood, 29 residents were killed or went missing, and many properties were damaged (Yoo and Choi, 2011). In July, 2011, the Mt. Umyeon landslide occurred in the center of Seoul Metropolitan City (Jun and Oh, 2011). Furthermore, a landslide from a mountain near the residential area of the Chuncheon holiday destination caused loss of life

and damage to properties. Considering this recent trend, it is clear that many landslides are regularly generated by typhoons or heavy rain and, accordingly, the damage caused is increasing. Therefore, it is necessary to scientifically analyze and systematically manage high landslide risk areas to effectively respond to the incidents. In addition, it is also necessary to investigate the causes of landslides and perform integrated analysis of high risk areas with historical evidence of past natural disasters. Recently, much research has been performed using GIS and remote sensing methods, together with spatial information databases integrating geography, hydrology, geology, and forestry to identify characteristics and causes of landslides. The Korea Forest Research Institute and the Korea Forest Service have developed and implemented the 'Landslide Risk Areas Management System' to prevent and manage landslides in a scientific way. The Korea Institute of Geoscience and Mineral Resources has also prepared a landslide prediction map (Chae and Cho, 2008). At present, there is a need for practical research based on this map to predict landslides more precisely and reduce the number of casualties of landslides.

The infinite slope stability model has been the most common method to evaluate slope stability and landslide risk using GIS technology, where the level of slope stability is defined based on slope angles and the catchment basin (Montgomery and Dietrich, 1994). A more sophisticated model integrating the infinite slope stability model with the dynamic modeling of hydrology has also been proposed (Wu and Sidle, 1995). A further method is SINMAP, used to analyze slope stability, which was developed by combining the infinite slope stability model and numerical modeling (Pack *et al.*, 1998).

Landslide susceptibility evaluation and prediction

have been established using GIS and RS methods (Kim *et al.*, 2005). For example, a study on highway avalanches was performed to estimate the locations and number of avalanches using SINMAP (Jang *et al.*, 2008). The Korea Forest Research Institute conducted a research to develop a method that can predict occurrence characteristics of avalanches and scale of damage (Oh *et al.*, 2006). The institute carried out a landslide case study using the SINMAP method and showed that it could be an effective tool in preliminary estimates of landslide risk in mountainous areas with steep slopes and thin soil layers. Furthermore, it is expected that this method can be applied effectively to identify high risk landslide areas with a hydrological interpretation of SINMAP, which was used to analyze the Mt. Umyeon landslide that occurred in 2011. In addition, the institute conducted risk analysis of basins affected by avalanches using GIS and to do this, it applied a statistical method consisting of SINMAP and seven parameters (angle of slope, country rock, condition of forest, length of slope, position of slope, shape of slope, and depth of soil) (Jun *et al.*, 2011).

Many landslide susceptibility analyses using GIS include probabilistic, statistical and artificial neural network analyses. The Likelihood Ratio based on Bayesian analysis can quantitatively emphasize an area vulnerable to landslides by calculating the likelihood ratio between landslide affected and other areas (Chung and Fabbri, 1998). To test the validity of the results, several probabilistic methods are usually compared using landslide occurrence positions of two groups that are temporally separated from each other (Chung and Fabbri, 1999). A study modeled landslide susceptibility of Colorado, USA using the weight of evidence technique (Regmi *et al.*, 2010). Another study conducted research on landslide susceptibility using the entropy of the latest GIS (Pourghasemi *et al.*, 2012), while in the conditional probabilistic model index is used to compare and evaluate landslide maps using three methods: frequency ratio, weights of evidence and logistic regression (Ozdemir and Altural, 2013).

**Fig. 1.** Flow chart of the work methodology.

In this study, we construct a database of different geographic-spatial information in the GIS environment to evaluate landslide susceptibility and to find potential risk areas by applying the GIS based SINMAP and Likelihood Ratio methods. We also carried out slope stability analysis using SINMAP (the deterministic method) to identify its correlation to occurrence of landslides, analyzed the relationship between landslide and other geographical spatial features by applying the Likelihood Ratio (the probabilistic method), and drew cartography of the disaster to reflect landslide susceptibility. The methodology is shown in (Figure 1).

## METHODS

### 1. The SINMAP method

The SINMAP methodology is based on the infinite-slope stability model (Hammond *et al.*, 1992) that balances (with edge effects neglected) destabilizing components of gravity against stabilizing components of friction and cohesion on a failure plane parallel to the ground surface. Based on the infinite-slope form of the Mohr-Coulomb failure law, as expressed by the ratio of stabilizing forces (shear strength) to destabilizing forces (shear stress) on a failure plane parallel to the surface, the safety factor calculation in SINMAP is

$$FS = \frac{C_r + C_s + \cos^2 \theta [\rho_s g (D - D_w) + (\rho_s g - \rho_w g) D_w] \tan \phi}{D \rho_s g \sin \theta \cos \theta} \quad \text{.....equation 1}$$

where,  $C_r$  is the root cohesion (N/m<sup>2</sup>),  $C_s$  is the soil cohesion (N/m<sup>2</sup>),  $\theta$  is the slope angle (°),  $\rho_s$  is wet soil density (kg/m<sup>3</sup>),  $\rho_w$  is the density of water (kg/m<sup>3</sup>),  $g$  is gravitational acceleration (9.81 m/s<sup>2</sup>),  $D$  the vertical soil depth (m),  $D_w$  the vertical height of the water table within the soil layer (m), and  $\phi$  the internal friction angle of the soil (°). The slope angle,  $\theta$ , is the arc tangent of the slope,  $S$ , expressed as a decimal drop per unit horizontal distance. Figure 2 illustrates the geometry assumed in equation (1). Soil thickness,  $h$  (m), and depth,  $D$ , are related by  $h = D \cos \theta$ . With this change FS reduces to

$$FS = \frac{C + \cos \theta [1 - wr] \tan \phi}{\sin \theta} \quad \text{.....equation 2}$$

$C$ ,  $w$ , and  $r$  denote the dimensionless cohesion, wetness

**Fig. 2.** The geometry of the assumed infinite slope stability model and parameters involved in the safety factor.

index, and density ratio, respectively, and are defined in the context of SINMAP as shown below

$$C = \frac{(C_r + C_s)}{(h\rho_w g)} \dots\dots\dots \text{equation 3}$$

$$w = \frac{D_w}{D} = \text{Min} \left( \frac{Ra}{T \sin \theta}, 1 \right) \dots\dots\dots \text{equation 4}$$

$$r = \frac{\rho_w}{\rho_s} \dots\dots\dots \text{equation 5}$$

The term  $R$  which appears in the wetness index equation, equation (3), is the effective recharge, Term  $a$  which also appears in the same equation stands for the specific catchment area defined as the upslope area per unit contour length with units  $m^2/m$ . As shown in Figure 2  $h$  is the depth to the plane of failure measured in a direction perpendicular to the ground surface, and  $r$ , as defined by equation (5), is water to saturated soil density ratio. The complete description of SINMAP model for a particular region of interest requires 2 variables and 3 parameters, as follows:

Variables:  $\theta$  and  $\alpha$

Parameters:  $C$ ,  $\phi$ , and the ratio  $R/T$

The variables are implicitly inputted in the form of a digital elevation model, DEM, for the model to calculate them from inbuilt modules for each and every pixel. An inventory of landslide initiation points is utilized for validating the model output (Fowze *et al.*, 2012). SINMAP holds the soil density ratio constant and allows variability in the soil cohesion, internal friction angle, and  $R/T$  using a uniform probability distribution given a specified lower and upper limit. SINMAP expresses the terrain stability by six broad classes with subjective breakpoints (Table 1).

## 2. The Likelihood Ratio method

The Likelihood Ratio is a data-driven method that is basically the Bayesian approach in a log-linear form using the prior and posterior probability, and is applied where sufficient data are available to estimate the relative importance of evidential themes by probability means.

In the Bayesian approach, sureness measures obey the basic axioms of probability theory and the basic expressions are statements about the prior, likelihood and posterior probabilities.

One of main concepts for applications is that the prior probability is successively updated with the addition of new evidence, so that the posterior probability from adding one piece of evidence can be treated as the prior probability for adding a new piece of evidence.

For a given number of units cells,  $N\{D\}$ , containing an occurrence,  $D$ , and the total number of unit cell in the study area,  $N\{T\}$ , the prior probability of an occurrence is expressed by

$$P\{D\} = \frac{N\{D\}}{N\{T\}} \dots\dots\dots \text{equation 6}$$

Supposing that a binary predictor pattern,  $B$ , occupying  $N\{F\}$  unit cells, occurs in the region, and that a number of known landslides occurs preferentially within the pattern, i.e.,  $N\{D|F\}$ , then the favorability of locating an occurrence, given the presence of a predictor and the absence of a pattern, can be expressed by the conditional probabilities.

$$P\{D|F\} = \frac{P\{D \cap F\}}{P\{F\}} = P\{D\} \frac{P\{F|D\}}{P\{F\}} \dots\dots \text{equation 7}$$

$$P\{D|\bar{F}\} = \frac{P\{D \cap \bar{F}\}}{P\{\bar{F}\}} = P\{D\} \frac{P\{\bar{F}|D\}}{P\{\bar{F}\}} \dots\dots \text{equation 8}$$

The posterior probability of an occurrence given the presence and absence of the predictor pattern are

**Table 1.** Classes of slope stability based on values of the Stability Index (SI)

Condition	Class	Predicted state	Parameter range	Passible influence of factors not modeled
$SI > 1.5$	1	Stable slope zone	Range cannot model instability	Significant destabilizing factors are required for instability
$1.5 > SI > 1.25$	2	Moderately stable slope zone	Range cannot model instability	Moderate destabilizing factors are required for instability
$1.25 > SI > 1.0$	3	Quasi-stable slope zone	Range cannot model instability	Minor destabilizing factors could lead to instability
$1.0 > SI > 0.5$	4	Lower threshold slope	Pessimistic half of range required for instability	Destabilizing factors are not required for instability
$0.5 > SI > 0.0$	5	Upper threshold slope	Optimistic half of range required for stability	Stabilizing factors may be responsible for stability
$0.0 > SI$	6	Defended slope zone	Range cannot model instability	Stabilizing factors are required for stability

denoted by  $P\{D|F\}$  and  $P\{D|\bar{F}\}$ , respectively;  $P\{D|F\}$  and  $P\{\bar{F}|D\}$  are the posterior probabilities of being inside and outside the predictor pattern,  $F$ , respectively, given the presence of an occurrence,  $D$ . Furthermore,  $P\{F\}$  and  $P\{\bar{F}\}$  are the prior probabilities of being inside and outside the predictor pattern, respectively. The same model can be expressed in an odds-type formulation, where the odds,  $O$ , are defined as  $O=P/(1-P)$ . Expressed as odds, equation (7) and (8), respectively, become

$$O\{D|F\} = O\{D\} \cdot \frac{P\{\bar{F}|D\}}{P\{\bar{F}|\bar{D}\}} \dots\dots\dots\text{equation 9}$$

$$O\{D|\bar{F}\} = O\{D\} \cdot \frac{P\{F|D\}}{P\{F|\bar{D}\}} \dots\dots\dots\text{equation 10}$$

where  $O\{D|F\}$  and  $O\{D|\bar{F}\}$  are the posterior odds of an occurrence given the presence and absence of a binary predictor pattern, respectively, and  $O\{D\}$  is the prior odds of an occurrence.

## THE STUDY AREA

We selected Injegun and the surrounding area of Gangwondo as the study area for landslide analysis (Figure 3). Landslide occurrence points were drawn from overlay analysis of airborne pictures taken before and after landslides in 2005 and 2006, and from site monitoring activities. In 2006, many landslides occurred in this area due to Typhoon Ewiniar and heavy rains. The total rainfall for this region for July 12–16, 2006 was 569.6mm. The highest recorded amount of rainfall during this period was 192 mm on July 15, and 65.5 mm was recorded as the highest hourly rainfall. As landslides have different patterns and occurrence frequencies, it is difficult to

select a standard quantitative value for each landslide factor. Therefore, it is necessary to analyze the spatial correlation between landslide occurrence positions and each landslide factor using GIS once the landslide factors have been selected.

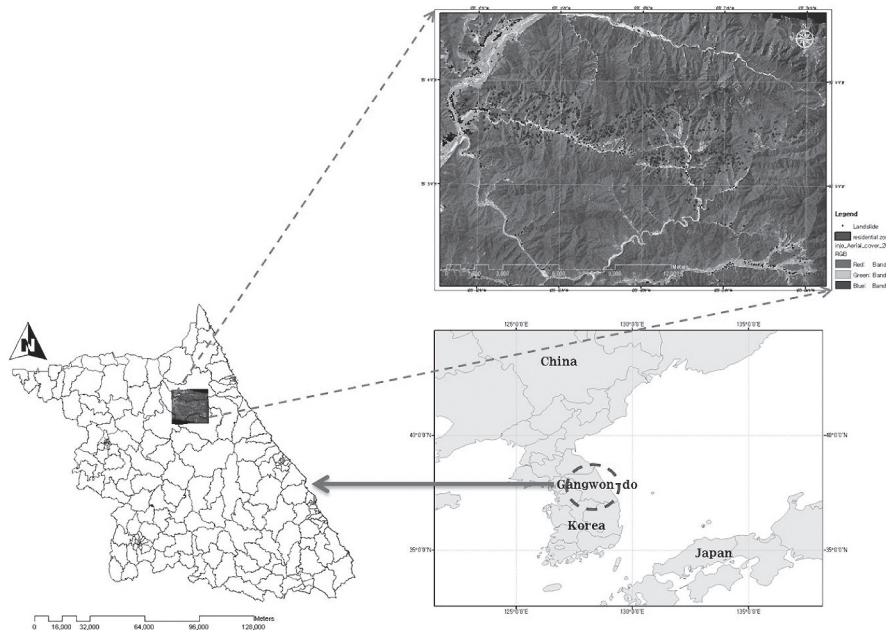

## RESULTS AND DISCUSSION

### 1. Application of the SINMAP model

This study identifies the levels of slope stability for landslide occurrence in the target area using SINMAP. This method is used to evaluate the moment of stability by applying inducing factors (such as geographical features, quality of soil, and climate) to a hydrological or a slope stability model including geography, and using a deterministic method that is based on physics and dynamics. Based on our findings (Figure 4), the area of  $SI < 0.5$  and  $1.0 < SI < 0.5$  was  $17.5 \text{ km}^2$  and  $109 \text{ km}^2$ , respectively. In other words, 44% of the total forest area ( $285 \text{ km}^2$ ) can be classified as landslide risk area. Conversely, approximately 25% ( $72 \text{ km}^2$ ) of the total study area can be regarded as stable area ( $SI > 1.5$ ). The final landslide risk area was estimated with overlay analysis using records of historical landslide occurrence, casualties, and property damage in the area. Table 2 shows the results of SINMAP for the selected basins. Approximately  $12 \text{ km}^2$ , which equals 36% of the total basin area ( $33.64 \text{ km}^2$ ), can be included in the risk area.

### 2. Application of the Likelihood Ratio model

The likelihood ratio, which is obtained on the basis of conditional probabilities, is equal to the ratio of the landslide area by the level of each factor. If the likelihood ratio is 1, the probability of landslide occurrence is the average compared with other landslide inducing factors. If the ratio is greater than 1, the probability of landslide occurrence is relatively high. If the ratio is less

**Fig. 3.** Study area and an aerial image map of landslides (2006).

**Table 2.** Classes of slope stability based on value of the Stability Index (SI)

	Stable (S)	Moderately Stable (MS)	Quasi- Stable (QS)	Lower Threshold (LT)	Upper Threshold (UT)	Defended (D)	Total
Area (km <sup>2</sup> )	10.0	4.7	7.0	11.0	0.9	0.04	33.64
% of Region	30	14	21	33	3	0	100

**Fig. 4.** Stability index map.

than 1, the probability of landslide occurrence is relatively low. To identify the characteristics of landslide occurrence locations, the factors are classified into appropriate groups to ensure that the attributes of each factor reflect its original value well. Using this process, the number of landslides that occurred in each class can be statistically identified.

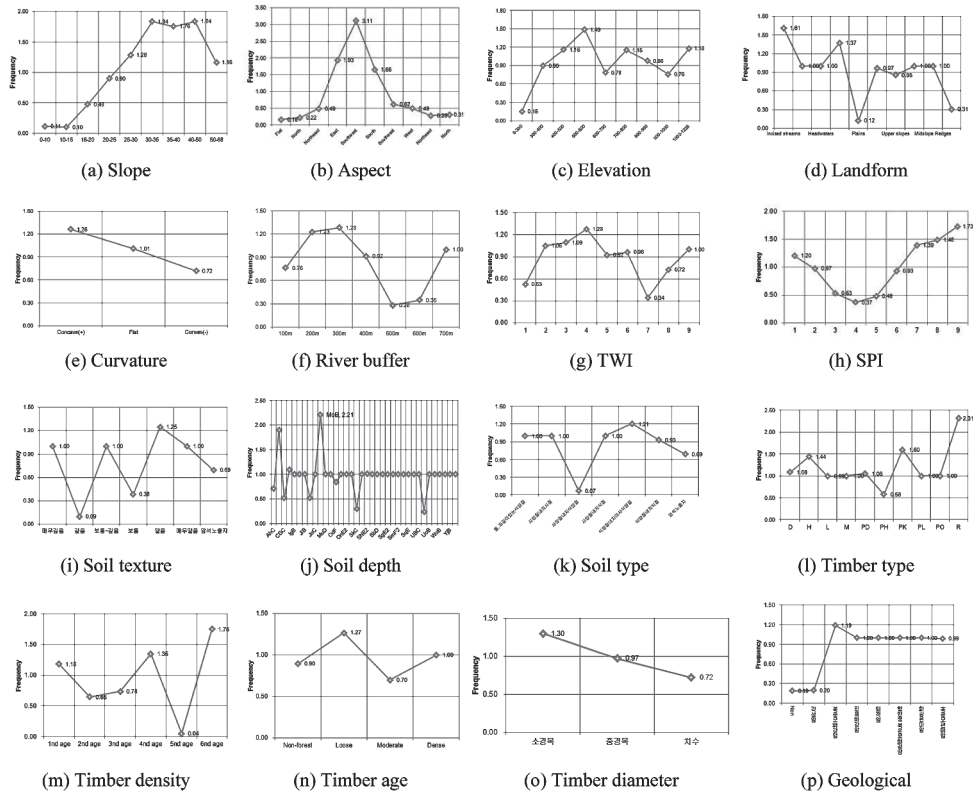

We produced a database to perform likelihood ratio analysis on basin areas selected in the SINMAP analysis.

This method also configures points, lines, faces, and coordinates, which are attributes of each factor required to prepare prediction, and builds 16 types of spatial databases, including geography, hydrology, geology, forestry, and geology (Figure 5).

For the relationship between landslide and geographical factors, the likelihood ratio of a slope of greater than 25° (Figure 6(a)) is more than 1, which shows that the probability of landslide occurrence is significantly increased. For the slope aspect (Figure 6(b)), the probability of landslide occurrence was high in the East and Southeast, and very high in the South with a probability of 3.11. For altitude (Figure 6(c)), the highest probability of landslide occurrence was found between 500–600 m, measuring 1.49. Landform (Figure 6(d)) was divided into 10 levels from flat ground, and ridge to the top of a mountain. According to the results, the likelihood ratio of a deep and a flat valley were 1.61 and 1.37, respectively. For curvature (Figure 6(e)), the negative value means that the slope plane is concave, while a positive value indicates that the slope plane is convex. Zero (0) shows that the slope plane is flat. The value of curvature is correlated to the convex area with 1.26.

Hydrological factors were analyzed using a buffer

**Fig. 5.** Maps in the spatial database used for landslide susceptibility analysis.

**Fig. 6.** Likelihood ratio between Mountainous disaster and related Factor.

zone, which was 100 m in length along a river, to measure correlation between basin areas and landslide occurrence positions, as shown in Figure 6(f). According to the results of the likelihood ratio, the values for 200 m and 300 m were 1.23 and 1.28, respectively. In fact, 90% of the landslide occurrence positions in the target area were located within 300 m of the river. Values for the TWI (Topographic Wetness Index) factor from 0 to 23.7 are divided into nine levels, which are in inverse proportion to the values of the slope. According to the results, level 4 had the highest probability value with 1.28. As seen in Figure 6(g), it has a negative relationship with landslide occurrence, unlike the slope. SPI (Stream power Index) (Figure 6(h)), a factor indicating the area of sloped basin, was analyzed with nine subgroups between 4.12 and -4.37. Classes 8 and 9, which have a high SPI value, had probabilities of 1.48 and 1.73, respectively.

Soil was analyzed by a code (Figure 6(i)) using a detailed soil map. The highest likelihood ratio was found in the Soil Code Mob with 2.21. Soil depth (Figure 6(j)) consists of categories of 'Very Deep', 'Deep', 'Moderate', 'Thin', 'Very Thin', and 'Rock Exposed'. The highest likelihood ratio, of 1.25, was found in the 'Thin' area. For the soil types, clay loam or silt clay loam has a probability of 1.21.

The relationship between forestry factors, including Timber type, Timber density, Timber age, and Timber diameter, was identified. For Timber type (Figure 6(l)), the non-forest area (R) had the highest value (2.31). Deciduous and *Pinus koraiensis* forests also had a high

probability (1.44 and 1.60, respectively). For Timber density (Figure 6(m)), the low density area had higher probability of landslides occurrence than the high density area. Timber had high correlation at age four and six years of 1.35 and 1.75, respectively (Figure 6(n)). For Timber diameter (Figure 6(o)), the timber with a small diameter had a 1.30 probability. For the geological features, a 1.19 probability value was found for Two-Mica Granite (Figure 6(p)).

Landslides Susceptibility Index by likelihood ratio (LR) was calculated from an overlay analysis, as shown in equation (11), which was calculated by allocating a likelihood ratio to a class of each factor. Figure 7 shows the predictions of landslide risk areas that are constructed by overlapping areas with high correlation. The Landslides Susceptibility Index areas are classified into 5%, 10%, 15%, and 70% to indicate risk levels of Very high, High, Medium, and Low.

$$LSI_{LR} = LR_1 + LR_2 + LR_3 + \dots + LR_n \dots \text{equation 11}$$

where  $LR_n$  is the likelihood ratio of each factor type or range.

The prediction rate curve (Figure 8) illustrates how well the estimators perform with respect to the landslides used in constructing the estimators [20]. The range was classified by area, which was equal to approximately 5%. The prediction rate measures how well the model predicts the distribution of future landslides. To calculate the prediction rate, we first counted the number of pixels of validated landslides in the landslide hazard level

whose value is greater than (100 minus a specific value) %. The percentage was then divided by the total number of pixels of validated landslides to obtain a normalized prediction rate. The prediction rate curve is the cumulative version of the prediction rate. It has the form  $y = \text{function}(x)$ . Here,  $x$ , ranging from 0 to 100%, is the percentage of relative landslide hazard, and corresponds to the legend in the prediction map (Figure 7). The value  $y$  is the percentage of occurrences predicted within the most favorable  $x$  of the study area. For example, in the most hazardous top 30% of areas, the prediction powers of the likelihood ratio were approximately 73%.

## CONCLUSIONS

We applied a GIS based SINMAP model and the Likelihood Ratio to predict landslide risk areas, which can be caused by heavy rains or typhoons in a mountainous area.

We produced maps of landslide occurrence points using the GIS method and airborne images, and constructed a spatial database using geographical, soil, hydrological, and geological factors. We also obtained a slope stable index by applying the SINMAP model to the target area affected by many landslides caused by heavy rains

and Typhoon Ewiniar in 2006, and applied the likelihood ratio model to the basin that had sustained extensive damage in its residential areas. We predicted landslide risk areas and prepared a susceptibility map after conducting overlay analysis of areas with high correlation, which were found using correlation analysis between each factor and landslide occurrence. The Landslides Susceptibility Index is classified into 5%, 10%, and 15%, 70%. We show that 73% of the total points are located in a relatively high risk section (areas classified between Very high and medium, which equal 30% of the total section). This indicates a relatively high correlation with actual landslide occurrences. We expect that these findings can be effective tools in preparing a risk map of mountain regions or locations close to residential areas.
