(Received 20 December 2010; published 25 May 2011)

Recently, the stationary state of a parallel-update totally asymmetric simple exclusion process with varying system length, which can be regarded as a queuing process with excluded-volume effect (exclusive queueing process), was obtained [C. Arita and D. Yanagisawa, J. Stat. Phys. 141, 829 (2010)]. In this paper, we analyze the dynamical properties of the number of particles (\(N_t\)) and the position of the last particle (the system length) (\(L_t\)), using an analytical method (generating function technique) as well as a phenomenological description based on domain-wall dynamics and Monte Carlo simulations. The system exhibits two phases corresponding to linear convergence or divergence of (\(N_t\)) and (\(L_t\)). These phases can both further be subdivided into high-density and maximal-current subphases. The predictions of the domain-wall theory are found to be in very good agreement quantitively with results from Monte Carlo simulations in the convergent phase. On the other hand, in the divergent phase, only the prediction for (\(N_t\)) agrees with simulations.

I. INTRODUCTION

Queueing processes have been studied extensively, especially due to their practical relevance [1–3]. They have been applied, e.g., to pedestrian queues [4], supply chains [5], human activities [6] or vehicular traffic [7,8], and other kinds of jamming phenomena. However, usually the spatial structure of the queues is neglected and the particles in the queues do not interact with each other. On the other hand, the totally asymmetric simple exclusion process (TASEP), which has a spatial structure and excluded-volume effect (hard-core repulsion), is one of the best-studied interacting particle systems [9]. Nowadays, the TASEP is a basic model for pedestrian and traffic flows [10,11].

Recently, a queueing process with the excluded-volume effect, the exclusive queueing process (EQP), was introduced in [12] and [13] independently, where the model was formulated as continuous-time and discrete-time Markov processes, respectively. This model can be rephrased as the TASEP on a semi-infinite chain with a new boundary condition; see Fig. 1. The left end is interpreted as the end of the queue where new customers arrive. Therefore, particles can enter at the left side next to the leftmost occupied site. The (fixed) rightmost site corresponds to the server. Here particles can leave the system after getting service. In the bulk a particle can hop to its right nearest-neighbor site if the target site is empty. After the study [13], where the bulk hopping rule is deterministic, the model with discrete time and probabilistic bulk hopping was analyzed [14].

Earlier works [12–14] focused on the exact probability distribution, physical quantities in the stationary state, and the conditions under which the EQP converges to the stationary state. In this paper, we study the dynamical properties by considering the number of particles and the system length, which is defined as the position of the leftmost particle. We use the same formalism as in [13,14], i.e., discrete time and parallel-update scheme. For the generic hopping probability \(p\), we will introduce a domain-wall prediction, checking it by Monte Carlo simulations. In the deterministic hopping case \(p = 1\), a rigorous analysis is available by using the generating function technique [15].

This paper is organized as follows. In Sec. II, we define the model as a discrete-time Markov process and review its stationary state based on [14], which can be generalized to the inhomogeneous injection case; see also Appendix A. In Sec. III, we introduce a phenomenological argument on how the number of particles (\(N_t\)) and the system length (\(L_t\)) converge or diverge, showing simulation results. In Sec. IV, we derive the asymptotic behaviors of (\(N_t\)) and (\(L_t\)) rigorously for \(p = 1\), imposing the initial condition that there is no particle on the chain. Section V is devoted to the conclusion of this paper.

II. MODEL

The EQP is defined on a semi-infinite chain where sites are labeled by natural numbers from right to left (Fig. 2). Particles can enter the chain with probability \(\alpha\) only at the left site next to the leftmost occupied site. A particle hops to its right nearest-neighbor site with probability \(p\), if it is empty, and exits at the right end of the chain with probability \(\beta\). If there is no particle on the chain, a particle enters at site 1 with probability \(\alpha\). These transitions occur simultaneously within one time step, i.e., we apply the fully parallel-update scheme.

We formulate the EQP as a discrete-time Markov process on the state space

\[ S = \{\emptyset, 1, 10, 11, 100, 101, 110, 111, 1000, \ldots\}, \tag{1} \]

where 0 and 1 correspond to unoccupied and occupied sites, respectively. In particular, \(\emptyset\) denotes the state in which there
is no particle on the chain. To simplify the notation, we do not write the infinite number of 0’s located left of the leftmost 1.

Let us review the matrix product stationary state [14] of the model, which is a simple extension of that for systems with a fixed system length [16]. When

\[ \begin{align*}
\alpha &\leq \alpha_c = \frac{1-\sqrt{1-p}}{2} & \text{for } \beta > 1 - \sqrt{1-p}, \\
\alpha &< \alpha_c = \frac{\beta(p-\beta)}{p-p^2} & \text{for } \beta \leq 1 - \sqrt{1-p},
\end{align*} \]

the stationary state can be expressed as

\[ P(\emptyset) = \frac{1}{Z}, \]

\[ P(1\tau_{l-1} \ldots \tau_1) = \frac{1}{Z} \left( \frac{\alpha}{p(1-\alpha)} \right)^L \langle W|DX_{\tau_{l-1}} \cdots X_{\tau_1}|V \rangle. \]

\[ (4) \]

\[ X_1 = D \text{ and } X_0 = E \] are matrices, \( \langle W \rangle \) is a row vector, and \( |V\rangle \) is a column vector satisfying the algebraic relations

\[ EDEE = (1-p)EDE + EEE + pEE, \]
\[ EDED = EDD + EED + pED, \]
\[ DDEE = (1-p)DDE + (1-p)DDE + p(1-p)DE, \]
\[ DDED = DDS + (1-p)DED + pDD, \]
\[ DDE|V\rangle = (1-\beta)DD|V\rangle + (1-p)DE|V\rangle + (p(1-\beta))D|V\rangle, \]
\[ EDE|V\rangle = (1-\beta)ED|V\rangle + EE|V\rangle + pE|V\rangle, \]
\[ \langle W|DEE = (1-p)\langle W|DE, \]
\[ \langle W|DED = \langle W|DD + p\langle W|D, \]
\[ DD|V\rangle = \frac{p(1-\beta)}{\beta} D|V\rangle, \]
\[ E|V\rangle = \frac{p}{\beta} E|V\rangle, \]
\[ \langle W|E = 0, \langle W|ED = p\langle W|D, \langle W|D|V\rangle = \frac{p}{\beta} \]

These relations are closely related to those for the stationary state of the parallel-update TASEP with ordinary open boundary condition [17]. The normalization constant is expressed as

\[ Z = 1 + \sum_{L \geq 1} \left( \frac{\alpha}{p(1-\alpha)} \right)^L \langle W|D(D+E)^{L-1}|V \rangle \]

\[ = \frac{2(1-\alpha)\beta}{R - p + 2(1-\alpha)\beta}, \]

\[ (6) \]

\[ (7) \]

with \( R = \sqrt{p(p - 4\alpha(1-\alpha))} \). The average number of particles \( \langle N \rangle \) and the average system length (the position of the leftmost particle) \( \langle L \rangle \) are calculated as

\[ \langle N \rangle = \alpha(1-\alpha)(p-2\alpha p + R) \]
\[ \langle L \rangle = \frac{\alpha p(R - p + 2(1-\alpha)\beta)}{R(R - p + 2(1-\alpha)\beta)}, \]

\[ (8) \]
\[ (9) \]

in the stationary state. Note that \( \langle N \rangle \) and \( \langle L \rangle \) diverge on the critical line \( \alpha = \frac{1}{4}(1-\sqrt{1-p}) \) and \( \beta > 1 - \sqrt{1-p} \), where the stationary state exists.

A generalization of the model, where the entry probability depends on the system length, also has a matrix product stationary state; see Appendix A.

III. DOMAIN-WALL PICTURE AND MONTE CARLO SIMULATIONS

In this section, we discuss the time evolution of the average number of particles \( \langle N_t \rangle \) and the average system length \( \langle L_t \rangle \) corresponding to the position of the leftmost particle.

In the ordinary open boundary case, where the length of the system is fixed, a domain wall moves rightward or leftward, or exhibits a random walk depending on the boundary parameters [18]. In the same way, we will discuss how the system length \( \langle L_t \rangle \) moves. We also observe how the average number of particles \( \langle N_t \rangle \) changes as well. The continuity equation

\[ \langle N_{t+1} \rangle - \langle N_t \rangle = J_{t}^\text{in} - J_{t}^\text{out} \]

holds, where \( J_{t}^\text{in} \) and \( J_{t}^\text{out} \) are the flows of particles entering and leaving the system, respectively. The inflow \( J_{t}^\text{in} \) is always \( \alpha \), which is due to the fact that the site where particles enter is by definition never blocked. In other words, our model is not a call-loss system. Under the assumption that the outflow \( J_{t}^\text{out} \) is independent of \( t \), we have \( \langle N_t \rangle = (\alpha - J_t^\text{out})t + \langle N_0 \rangle \). In fact, our simulations show that both \( \langle N_t \rangle \) and \( \langle L_t \rangle \) decrease or increase linearly in time \( t \) according to \( \alpha < \alpha_c \) or \( \alpha > \alpha_c \), respectively.
The markers × and □ present data for $\langle N_t \rangle$ and $\langle L_t \rangle$, respectively, obtained from Monte Carlo simulations, where 5000 samples are averaged. The lines correspond to the predictions of the domain-wall theory. Note that the asymptotic values are small but nonzero [see Eqs. (8) and (9)]; $\langle N_\infty \rangle = (1.70, 2.28)$ and $\langle N_{\infty} \rangle = (0.42, 0.56)$, respectively.

A. Convergent phase

When $\alpha < \alpha_c$, the system converges to the stationary state (3) and (4). We impose the initial condition that particles are distributed uniformly with density

$$\rho = \begin{cases} \frac{1}{2} & \text{for } \beta > 1 - \sqrt{1 - p}, \\ \frac{\beta - \rho}{p - \rho} & \text{for } \beta \leq 1 - \sqrt{1 - p}. \end{cases} \quad (11)$$

As in Fig. 3, $\langle N_t \rangle$ and $\langle L_t \rangle$ decrease linearly in time as

$$\langle N_t \rangle \sim (\alpha - J_{\text{out}}) t + \langle N_0 \rangle, \quad \langle L_t \rangle \sim \frac{\alpha - J_{\text{out}}}{\rho} t + \langle L_0 \rangle, \quad (12, 13)$$

with

$$J_{\text{out}} = \frac{1 - \sqrt{1 - 4\rho p(1 - \rho)}}{2}$$

$$= \begin{cases} \frac{1 - \sqrt{1 - p}}{2} & \text{for } \beta > 1 - \sqrt{1 - p}, \\ \frac{\beta(p - \rho)}{p - \rho} & \text{for } \beta \leq 1 - \sqrt{1 - p}. \end{cases} \quad (14)$$

Since $J_{\text{out}} = \alpha_c$, we have $\alpha - J_{\text{out}} < 0$, which means that the domain wall moves rightward.

FIG. 3. Dynamics in the HD-C (top) and MC-C (bottom) phases. The parameter values are chosen as $(\alpha, \beta, p) = (0.2, 0.4, 0.84)$ and $(0.2, 0.8, 0.84)$, and the initial conditions as $\langle (N_0), (L_0) \rangle = (400, 400)$ and $\langle 600, 600 \rangle$ [with $\rho$ defined by Eq. (11)], respectively.

It should be noted that the outflow is given by Eq. (14) only while $0 \leq t < \frac{1}{\sqrt{1 - \rho}}$. As $t \to \infty$, the outflow approaches $\alpha$, assuring that $\langle N_t \rangle$ approaches the stationary value (8).

A. Convergent phase

When $\alpha < \alpha_c$, the system converges to the stationary state (3) and (4). We impose the initial condition that particles are distributed uniformly with density

$$\rho = \begin{cases} \frac{1}{2} & \text{for } \beta > 1 - \sqrt{1 - p}, \\ \frac{\beta - \rho}{p - \rho} & \text{for } \beta \leq 1 - \sqrt{1 - p}. \end{cases} \quad (11)$$

As in Fig. 3, $\langle N_t \rangle$ and $\langle L_t \rangle$ decrease linearly in time as

$$\langle N_t \rangle \sim (\alpha - J_{\text{out}}) t + \langle N_0 \rangle, \quad \langle L_t \rangle \sim \frac{\alpha - J_{\text{out}}}{\rho} t + \langle L_0 \rangle, \quad (12, 13)$$

with

$$J_{\text{out}} = \frac{1 - \sqrt{1 - 4\rho p(1 - \rho)}}{2}$$

$$= \begin{cases} \frac{1 - \sqrt{1 - p}}{2} & \text{for } \beta > 1 - \sqrt{1 - p}, \\ \frac{\beta(p - \rho)}{p - \rho} & \text{for } \beta \leq 1 - \sqrt{1 - p}. \end{cases} \quad (14)$$

Since $J_{\text{out}} = \alpha_c$, we have $\alpha - J_{\text{out}} < 0$, which means that the domain wall moves rightward.

FIG. 4. Subphases of the EQP.

According to the forms for $J_{\text{out}}$ and $\rho$, we call the phases

HD-C: $\alpha < 1 - \sqrt{1 - p}$ and $\beta > 1 - \sqrt{1 - p}$. \quad (15)

MC-C: $\alpha < \frac{\beta(p - \beta)}{\rho - \beta^2}$ and $\beta \leq 1 - \sqrt{1 - p}$. \quad (16)

maximal-current-convergent (MC-C) and high-density-convergent (HD-C) phases, respectively; see Fig. 4.

It should be noted that the outflow is given by Eq. (14) only while $0 \leq t < \frac{1}{\sqrt{1 - \rho}}$. As $t \to \infty$, the outflow approaches $\alpha$, assuring that $\langle N_t \rangle$ approaches the stationary value (8).

FIG. 5. Density profiles $\langle r_{j,t} \rangle$ of the $j$th site at time $t$ in the HD-C (top) and MC-C (bottom) phases. The parameters $(\alpha, \beta, p)$ and the initial conditions $\langle (N_0), (L_0) \rangle$ are set to the same values as in Fig. 3. The snapshots are obtained by averaging 5000 samples of Monte Carlo simulations. The straight lines represent the predicted densities $\rho$ according to Eq. (11).
and we have exactly $\langle L_i \rangle = t + \langle L_0 \rangle$ when $\alpha = 1$. Moreover, when $p = 1$, we will show in the next section that

$$V = \alpha - \beta + \alpha\beta = \frac{\alpha - \beta}{1 + \beta} = \frac{\alpha - J^\text{out}}{\rho}. \quad (21)$$

Equations (17) and (18) can be regarded as the asymptotic behaviors

$$\langle N_i \rangle = (\alpha - J^\text{out})t + o(t), \quad (22)$$

$$\langle L_i \rangle = Vt + o(t). \quad (23)$$

In the same way as in the convergent phase, we call the subphases

- **MC-D**: $\alpha > 1 - \frac{\sqrt{1 - p}}{p}$ and $\beta > 1 - \frac{\sqrt{1 - p}}{2}$, respectively.
- **HD-D**: $\alpha < \frac{\beta(p - \beta)}{p - \beta^2}$ and $\beta < 1 - \frac{\sqrt{1 - p}}{2}$, respectively.

It is difficult to predict how $\langle N_i \rangle$ or $\langle L_i \rangle$ behaves just on the critical line $\alpha = \alpha_c$. For $p = 1$, however, we will find in the next section diffusive behavior on the critical line as

$$\langle N_i \rangle = D_N \sqrt{t} + o(\sqrt{t}), \quad (26)$$

$$\langle L_i \rangle = D_L \sqrt{t} + o(\sqrt{t}) \quad (27)$$

with constants $D_N$ and $D_L$.

## IV. ASYMPTOTIC BEHAVIORS FOR $p = 1$

In this section we investigate the asymptotic behaviors of $\langle N_i \rangle$ and $\langle L_i \rangle$ rigorously for $p = 1$. Thanks to the deterministic particle hopping, we can obtain the generating functions of $\langle N_i \rangle$ and $\langle L_i \rangle$. For simplicity, we impose the initial condition

![Figure 7](image-url)

**FIG. 7.** Phase diagram for $p = 1$. 

---

**Figure 5** shows density profiles in the HD-C and MC-C phases. We can observe that the bulk density keeps its initial value (11).

### B. Divergent phase

When $\alpha > \alpha_c$, it is natural to expect that the domain wall moves leftward, and the time evolutions of $\langle N_i \rangle$ and $\langle L_i \rangle$ are expressed by Eqs. (12) and (13), respectively, with the density $\rho$ and the initial conditions as $\langle N_0 \rangle$ and $\langle L_0 \rangle$. The simulations imply that this is true for $\langle N_i \rangle$ with

$$\langle N_i \rangle \sim (\alpha - J^\text{out})t + \langle N_0 \rangle, \quad (17)$$

but fails for $\langle L_i \rangle$; see Fig. 6. This failure is not unexpected since the predicted velocity $\frac{\alpha - J^\text{out}}{\rho}$ can be greater than 1, whereas the length $\langle L_i \rangle$ cannot be larger than $t + \langle L_0 \rangle$ by the definition of the model. However, the simulation results (see Fig. 6) indicate that

$$\langle L_i \rangle \sim Vt + \langle L_0 \rangle, \quad (18)$$

so that the prediction is qualitatively correct. The velocity $V$ satisfies

$$V \to 0 \quad (\alpha \to \alpha_c), \quad (19)$$

$$V = 1 \quad (\alpha = 1), \quad (20)$$

![Diagram](image-url)

**FIG. 6.** Dynamics in the HD-D (top) and MC-D (bottom) phases. The parameter values are chosen as $(\alpha, \beta, p) = (0.75, 0.4, 0.84)$ and $(0.75, 0.8, 0.84)$, respectively, and the initial conditions as $\langle N_0 \rangle, \langle L_0 \rangle = (200\rho, 200)$. The markers $\times$ and $\Box$ present data for $\langle N_i \rangle$ and $\langle L_i \rangle$ obtained from Monte Carlo simulations, where 1000 samples are averaged. The lines correspond to the predictions of the domain-wall theory.
∅ (there is no particle in the system at time \( t = 0 \)), and reset the state space as
\[
\tilde{S} := \{\emptyset, 1, 10, 11, 101, 110, 111, 1010, 1011, \ldots\} = \{\tau \in S | \tau \) does not contain sequence 00\}.
\] (28)

Note that, for \( p = 1 \), the sequence 00 never appears if the system starts from the initial condition \( \emptyset \). In this case, the MC-D and MC-C phases vanish from the phase diagram; see Fig. 7.

We first consider the number of particles, borrowing the classification from \[13\] as
\[
P_t^A(N) = \text{Prob}\left[ \begin{array}{c} \text{# of particles is } N \text{ at time } t \\ \wedge \text{ site 1 is occupied at time } t \end{array} \right],
\] (29)
\[
P_t^B(N) = \text{Prob}\left[ \begin{array}{c} \text{# of particles is } N \text{ at time } t \\ \wedge \text{ site 1 is empty at time } t \end{array} \right]
\] (30)
for \( N \in \mathbb{Z}_{\geq 0} \) with \( P_t^A(0) = 0 \). These probabilities are governed by the following master equation, which was found in \[13\]:
\[
P_{t+1}^A(1) = (1 - \alpha)(1 - \beta)P_t^A(1) + \alpha P_t^B(0) + (1 - \alpha)P_t^B(1),
\] (31)
\[
P_{t+1}^A(N) = \alpha(1 - \beta)P_t^A(N - 1) + \alpha P_t^B(N - 1) + (1 - \alpha)(1 - \beta)P_t^A(N) + (1 - \alpha)P_t^B(N),
\] (32)
\[
P_{t+1}^B(0) = (1 - \alpha)P_t^A(0) + (1 - \alpha)\beta P_t^A(1),
\] (33)
\[
P_{t+1}^B(N) = \alpha\beta P_t^A(N) + (1 - \alpha)\beta P_t^A(N + 1).
\] (34)

This simplification is due to the deterministic hopping \( p = 1 \). We choose the initial condition such that
\[
P_0^A(0) = 1, \quad P_0^B(N) = P_0^B(N) = 0 \quad (N \in \mathbb{N}).
\] (35)

We will check that the average number of particles \( \langle N_t \rangle \) converges to the stationary value (8) when \( \alpha < \frac{\sqrt{1-\beta}}{1+\beta} \), and show that \( \langle N_t \rangle \) behaves as Eq. (22) when \( \alpha > \frac{\sqrt{1-\beta}}{1+\beta} \). We will also show that \( \langle N_t \rangle \) exhibits diffusive behavior on the critical value \( \alpha = \frac{\sqrt{1-\beta}}{1+\beta} \).

We define the generating functions of \( P_t^A(N) \) and \( P_t^B(N) \) as
\[
G^A_z(N) = \sum_{t \geq 0} P_t^A(N)z^t,
\] (36)
\[
G^B_z(N) = \sum_{t \geq 0} P_t^B(N)z^t,
\] (37)
for \( |z| < 1 \). Noting the initial condition (35), we find
\[
G^A_z(1) = (1 - \alpha)(1 - \beta)zG^A_z(1) + \alpha zG^B_z(0) + (1 - \alpha)zG^B_z(1),
\] (38)
\[
G^A_z(N) = \alpha(1 - \beta)zG^A_z(N - 1) + \alpha zG^B_z(N - 1) + (1 - \alpha)(1 - \beta)zG^A_z(N) + (1 - \alpha)zG^B_z(N),
\] (39)
\[
G^B_z(0) - 1 = (1 - \alpha)zG^B_z(0) + (1 - \alpha)\beta zG^A_z(1),
\] (40)
\[
G^B_z(N) = \alpha\beta zG^A_z(N) + (1 - \alpha)\beta G^A_z(N + 1).
\] (41)

From Eq. (40), we have
\[
G^B_z(0) = \frac{1 + (1 - \alpha)\beta z}{1 - (1 - \alpha)z}.
\] (42)

Inserting this and Eq. (41) into Eqs. (38) and (39), we get a recurrence formula for \( G^A_z(N) \) as
\[
G^A_z(2) = \frac{1 - (1 - \alpha)(2 - \beta)z + (1 - \alpha)(1 - \alpha - \beta - \alpha\beta)z^2 + (1 - \alpha)^2\beta z^3}{(1 - \alpha)^2\beta[1 - (1 - \alpha)z]^2} G^A_z(1),
\] (43)
\[
G^A_z(N + 1) = \frac{1 - (1 - \alpha)(1 - \beta)z - 2(1 - \alpha)\alpha\beta z^2}{(1 - \alpha)^2\beta z^2} G^A_z(N) + \frac{\alpha(1 - \beta) + \alpha^2\beta z}{(1 - \alpha)^2\beta z} G^A_z(N - 1)
\] (44)
\[\implies : xG^A_z(N) + yG^A_z(N - 1) \quad (N \in \mathbb{Z}_{\geq 2}).\]

The recurrence formula (44) has the following solution:
\[
G^A_z(N) = \frac{\lambda_+^{N-1} - \lambda_-^{N-1}}{\lambda_+ - \lambda_-} \left[ G^A_z(2) - \lambda_- G^A_z(1) \right]
\] (46)
\[\implies : \lambda_\pm = \frac{1 - (1 - \alpha)(1 - \beta)z - 2(1 - \alpha)\alpha\beta z^2 \pm r}{2(1 - \alpha)^2\beta z^2} \quad (46)
\]
where
\[
G^A_z(N) < \sum_{t \geq 0} |z|^t = \frac{1}{1 - |z|},
\] (48)

we have
\[
G^A_z(2) - \lambda_- G^A_z(1) = 0.
\] (49)
Around the origin is determined as

\[ G_z^A(N) = \frac{1 - (1 - z) (2 - \beta) z - (1 - \alpha) (1 - \alpha - \beta - \alpha \beta) z^2 + [1 - (1 - \alpha) z]\sqrt{1 - z}}{2(1 - \alpha)^2 \beta^2 (1 - z)^2} \quad (N \in \mathbb{N}), \]

and

\[ G_z^B(0) = \frac{-1 + r + (1 - \alpha)(1 + \beta)z}{2(1 - \alpha) \beta z(1 - z)}, \quad G_z^B(N) = \frac{[\alpha + (1 - \alpha) \lambda_{-\alpha}] \beta z \lambda_{-\alpha}^{-1} G_z^A(1)}{(N \in \mathbb{N})}. \]

Then we obtain the generating function \( G_z(N) \) of the probability that the number of particles is \( N \) as

\[ G_z(0) = G_z^B(0), \quad G_z(N) = G_z^A(N) + G_z^B(N) = g(z)\lambda_N, \]

\[ g(z) = \beta - 1 + (1 - \alpha - \beta + \alpha \beta^2) z + (1 - \alpha)(1 - \beta) \beta z^2 + r [1 - (1 - z)^2] \quad (N \in \mathbb{N}). \]

We also introduce the generating function \( G_{\xi N} \) of the generating function \( G_z(N) \) as

\[ G_{\xi N} = \sum_{N \geq 0} G_N(z) \xi^N = G_0(z) + \sum_{N \geq 1} g(z)(\lambda_{-\xi})^N = G_0(z) + g(z) \frac{\lambda_{-\xi}}{1 - \lambda_{-\xi}}, \]

and \( K_z \) of the average number of particles as

\[ K_z = \sum_{t \geq 0} z^t \langle N_t \rangle = \sum_{t \geq 0} \sum_{N \geq 0} N \{ P_z^A(N) + P_z^B(N) \} = \frac{\partial}{\partial \xi} G_{\xi z} \bigg|_{\xi = 1} = \frac{z[2\alpha - 1 + z(1 - \alpha)(1 - \beta) + r]}{2(1 - z)^2 (1 + z \beta)}. \]

To investigate the asymptotic behavior of \( \langle N_t \rangle \), we use the following strategy [15,16]. For a function \( f(z) \), let \( z_0 \) be the singularity closest to the origin in the complex plane. Suppose that \( f(z) \) is decomposed as

\[ f(z) = (1 - z / z_0)^{-d} f_0(z), \]

with a function \( f_0(z) \) whose value at \( z = z_0 \) is nonzero and finite. We call here the exponent \( d > 0 \) order. The asymptotic behavior of the coefficient \( a_t \) of \( z^t \) in the power series of \( f(z) \) around the origin is determined as

\[ a_t = \frac{f_0(z_0)}{\Gamma(d)} z_0^t t^d + o(z_0^t t^d) \quad (t \to \infty) \]

with the Gamma function \( \Gamma(d) \).

For \( K_z \), the closest singularity is \( z_0 = 1 \), and its order can change depending on parameters \( \alpha \) and \( \beta \). When \( \alpha < \frac{\beta}{1 + \beta} \), we find

\[ (1 - z) K_z \big|_{z=1} = \frac{\alpha(1 - \alpha)}{\beta - \alpha - \alpha \beta}, \]

and \( \langle N_t \rangle \) converges as

\[ \langle N_t \rangle \to \frac{\alpha(1 - \alpha)}{\beta - \alpha - \alpha \beta} \quad (t \to \infty). \]

Of course, this limit value agrees with the stationary value (8) with \( p = 1 \). When \( \alpha > \frac{\beta}{1 + \beta} \), we find

\[ (1 - z)^2 K_z \big|_{z=1} = \frac{\beta}{1 + \beta}, \]

and \( \langle N_t \rangle \) behaves as

\[ \langle N_t \rangle = \left( \frac{\alpha - \beta}{1 + \beta} \right) t + o(t) \quad (t \to \infty). \]

When \( \alpha = \frac{\beta}{1 + \beta} \), we find

\[ (1 - z)^2 K_z \big|_{z=1} = \sqrt{\frac{\beta}{1 + \beta}}, \]

and \( \langle N_t \rangle \) behaves as

\[ \langle N_t \rangle = 2 \sqrt{\frac{\beta t}{\pi (1 + \beta)^3}} + o(\sqrt{t}) \quad (t \to \infty). \]

Now we turn to the behavior of the length of the system (the position of the leftmost particle). Let \( Q_t(L) \) be the probability that the system length is \( L \) at time \( t \). The probability \( Q_t(L) \) is governed by

\[ Q_{t+1}(0) = (1 - \alpha) Q_t(0) + \beta (1 - \alpha) Q_t(1), \]

\[ Q_{t+1}(L) = \alpha Q_t(L - 1) + (1 - \alpha)(1 - \beta) Q_t(L) + (1 - \alpha) \beta Q_t(L + 1) \]

for \( L \in \mathbb{N} \). The first equation means that, if there is no particle at time \( t + 1 \), there is no particle at time \( t \) and no particle enters (with probability \( 1 - \alpha \)), or there is only one particle on the rightmost site at time \( t \), which leaves the system and no particle enters [with probability \( (1 - \alpha) \beta \)]. The second equation is derived in Appendix B.

In the same way as for the number of particles, we define the generating function \( M_t(L) = \sum_{t \geq 0} z^t Q_t(L) \) (\( |z| < 1 \)). Noting the initial conditions \( Q_0(0) = 1 \) and \( Q_0(L) = 0 \) (\( L \in \mathbb{N} \)), we find

\[ M_t(1) = 1 - \frac{(1 - \alpha) z}{(1 - \alpha) \beta z} M_{t-1}(0) - \frac{1}{(1 - \alpha) \beta z}. \]
The solution to the recurrence formula (68) is
\[ M_z(L) = \frac{\Lambda^L_+}{\Lambda^L_+ - \Lambda_-} [M_z(1) - \Lambda_- M_z(0)] + \frac{\Lambda^L_-}{\Lambda^L_+ - \Lambda_-} [M_z(L) - \Lambda_+ M_z(0)], \]
where \( \Lambda_+ = \frac{1-\alpha(1-\beta)}{\xi^2(1-\beta)^2 L} \) and \( \Lambda_- = \frac{1-\beta}{\xi^2(1-\beta)^2 L} \) are the solutions to \( \Lambda^2 = \lambda \Lambda + \ldots \) with \( \lambda \) and \( \Lambda \) as defined in Eq. (68). Due to the condition \( |M_z(L)| < \frac{1}{\sqrt{\pi t}} \), the “initial condition” must be restricted as
\[ M_z(1) - \Lambda_- M_z(0) = 0. \] (70)
(Note that \( 0 < |\Lambda_-| < 1 < |\Lambda_+| \).) Thus we find
\[ M_z(L) = M_z(0) \frac{\Lambda^L_+}{1 - (1 - \alpha)(1 + \beta)z + r \Lambda^L_-}. \] (71)

The generating function of the generating function is calculated as
\[ M_{z\xi} = \sum_{L \geq 0} z^L M_z(L) = \frac{M_z(0)}{1 - \xi \Lambda_-}, \] (72)
and that of the average system length as
\[ S_z = \sum_{L \geq 0} z^L \langle L_t \rangle = \sum_{L \geq 0} z^L \sum_{L \geq 0} L Q_z(L) \]
\[ = \frac{\partial}{\partial \xi} M_{z\xi} \bigg|_{\xi = 1} = -1 + (1 + \alpha - \beta + \alpha \beta)z + r \frac{2(1 - z^2)}{2(1 - z)}. \] (73)

The singularity of \( S_z \), which is closest to the origin, is also \( z = 1 \), and the asymptotic behavior of \( \langle L_t \rangle \) is determined in the same way as for \( \langle N_t \rangle \). When \( \alpha < \frac{\beta}{1+\beta} \), we find
\[ (1 - z) S_z \big|_{z=1} = \frac{\alpha}{\beta - \alpha - \alpha \beta}, \] (74)
and \( \langle L_t \rangle \) converges as
\[ \langle L_t \rangle \to \frac{\alpha}{\beta - \alpha - \alpha \beta} \quad (t \to \infty). \] (75)
Again this limit value agrees with the stationary value (9) with \( p = 1 \). When \( \alpha > \frac{\beta}{1+\beta} \), we find
\[ (1 - z)^2 S_z \big|_{z=1} = \alpha - \beta + \alpha \beta, \] (76)
and \( \langle L_t \rangle \) behaves as
\[ \langle L_t \rangle = \frac{\alpha - \beta}{1+\beta} t + o(t) \quad (t \to \infty). \] (77)

When \( \alpha = \frac{\beta}{1+\beta} \), we find
\[ (1 - z)^2 S_z \big|_{z=1} = 1, \] (79)
and \( \langle L_t \rangle \) behaves as
\[ \langle L_t \rangle = 2 \frac{\beta t}{\pi(1+\beta)} + o(\sqrt{t}) \quad (t \to \infty). \] (80)

V. CONCLUSION

We have investigated the dynamical properties of the EQP, a queuing process with an excluded-volume effect. The model can be interpreted as a TASEP with varying length. Using generating function techniques and a phenomenological domain-wall theory, we have derived analytical predictions for the time dependence of the number of particles \( \langle N_t \rangle \) and the average system length \( \langle L_t \rangle \).

We found that the two phases observed previously can be divided in subphases. The convergent phase, where the system length remains finite, consists of high-density and maximal current subphases. The same is true for the diverging phase, where the system length becomes infinite in the long time limit.

By comparing with Monte Carlo simulations, it was found that the predictions of the domain-wall theory for the dynamical behavior are at least qualitatively correct, i.e., \( \langle N_t \rangle \) and \( \langle N_t \rangle \) converge or diverge linearly in time. Moreover, they are in good agreement even quantitively in the convergent phase. In the divergent phase, the predicted velocity for \( \langle N_t \rangle \) appears to be correct, whereas deviations from the domain-wall theory can be observed for \( \langle L_t \rangle \).

For \( p = 1 \), we derived exact analytical results for the behaviors of \( \langle N_t \rangle \) and \( \langle L_t \rangle \) by using the generating function method. We showed the linearity of their dynamics in the divergent phase as predicted by the domain-wall theory. We found diffusive behavior on the critical line as well.

The simple approach presented here does not provide a good expression for the velocity \( V \) of the system length \( \langle L_t \rangle \sim V t \) in the divergent phase. Here further analysis of the detailed density profiles in the divergent phase may be helpful. A first step would be the numerical determination of \( V \) to get a better understanding of its dependence on the parameters \( \alpha \), \( \beta \), and \( p \). Another way to settle the problem is extending the exact result to the \( p < 1 \) case, which may be difficult but very worthwhile.

APPENDIX A: STATIONARY STATE FOR INHOMOGENEOUS INJECTION CASE

Here we consider the stationary state for a generalized model where the entry probability depends on the system length. A new particle enters the system with probability \( \alpha_L \) if the leftmost occupied site is \( L \), or \( \alpha_0 \) if there is no particle on the chain. The stationary state of this generalized model can be written in the following matrix product form with the same
matrices and vectors \((D, E, \{W\}, \text{and } \{V\})\):

\[
P(\tau_L \cdots \tau_t) = \frac{1}{Z} \prod_{j=1}^{t-1} \frac{\alpha_j}{1-\alpha_j} \langle W | X_{\tau_t} \cdots X_{\tau_1} | V \rangle,
\]

\[
Z = 1 + \sum_{L \geq 1} \prod_{j=1}^{t-1} \frac{\alpha_j}{1-\alpha_j} \langle W | D(D+E)^{L-1} | V \rangle.
\]

This can be proved in the same way as in the homogeneous case \(\alpha_L = \alpha\); see [14].

**APPENDIX B: DERIVATION OF EQ. (66)**

To derive Eq. (66), we show

\[
\beta Q_t(L) \equiv \text{Prob} \left[ \text{the system length is } L \text{ at time } t \right] \wedge \left( L - 1 \right) \text{th site is empty at time } t \right],
\]

\[
(1-\beta)Q_t(L) \equiv \text{Prob} \left[ \text{the system length is } L \text{ at time } t \right] \wedge \left( L - 1 \right) \text{th site is occupied at time } t \right].
\]

for \(L \in \mathbb{N}_{\geq 2} \).

In the deterministic hopping case \(p = 1\) with the initial condition \(\emptyset\), the sequence 00 (except the infinite number of 0’s left of the leftmost particle) never appears, and holes necessarily “hop” leftward. Thus the first site must be occupied by a particle at time \(t - L + 1\) if the system length at time \(t\) is \(L\). The local state (empty or occupied) of the \((L - 1)\)th site at time \(t\) depends only on whether the first particle exits or not at time \(t - L + 1\). Let the number of particles be \(n\) at time \(t - L + 1\), and label the particles by natural numbers as in Fig. 8. We can show by induction that the \(\ell\)th particle is on the \(\ell\)th site at time \(t - L + \ell\). Thus we find that \(L - n\) new particles should enter the system during \([t - L + 1, t - 1]\).

The summation of all the transition probabilities from a configuration \(S^{(t-L+1)}\) at time \(t - L + 1\) to the states in which the system length is \(L\) and the \((L-1)\)th site is empty or occupied at time \(t\) is given by

\[
\sum_{S^{(t-L+1)} \rightarrow S^{(t+1)}} \prod_{t' = t - L + 1}^{t-1} W(S^{(t')}) \rightarrow S^{(t+1)} = \left\{ \begin{array}{ll}
\binom{L-1}{n} \alpha^{L-n} (1 - \alpha)^{n-1} \beta & (x = 0), \\
\binom{L-1}{n} \alpha^{L-n} (1 - \alpha)^{n-1} (1 - \beta) & (x = 1),
\end{array} \right.
\]

where \(W(S^{(t')}) \rightarrow S^{(t'+1)}), |S^{(t')}\rangle\), and \(\langle S^{(t')} |\) denote the transition probability from \(S^{(t')}\) to \(S^{(t'+1)}\), the length of the state \(S^{(t')}\), and the local state of site \(j\), respectively. The binomial \(\binom{L-1}{n}\) gives the number of possibilities for when the new particles enter the system. Equation (B3) leads to Eqs. (B1) and (B2).

If the length is \(L\) at time \(t + 1\), there are the following three possibilities at time \(t\): (i) the length is \(L - 1\) and a new particle enters (with probability \(\alpha\)), (ii) the length is \(L\), the \((L-1)\)th site is occupied, and no particle enters (with probability \(1 - \alpha\)), or (iii) the length is \(L + 1\), the \(L\)th site is empty, and no particle enters (with probability \(1 - \alpha\)).

Then we achieve Eq. (66) for \(L \in \mathbb{Z}_{\geq 2}\). For \(L = 1\), case (ii) is replaced by the following: the length is \(1\), the particle at the rightmost site does not leave, and no particle enters [with probability \((1 - \alpha)(1 - \beta)\)].
