Analytical model for determining effective stiffness and mechanical behavior of polymer matrix composite laminates using continuum damage mechanics

Sota Onodera¹ and Tomonaga Okabe¹,²

Abstract
The present paper proposes a new analytical model for predicting the effective stiffness of composite laminates with fiber breaks and transverse cracks. The model is based on continuum damage mechanics and the classical laminate theory. We derived damage variables describing stiffness reduction due to fiber breaks and its maximum value during ultimate tensile failure from the global load-sharing model. Furthermore, a simplified analytical model is presented for obtaining two damage variables for a cracked ply subjected to transverse tensile loading or in-plane shear loading. This model was developed assuming that the displacement field of the longitudinal direction can be expressed in the form of a quadric function by loosening the boundary condition for the governing differential equation. For verifying the developed model, the elastic constants of damaged composite laminates were predicted for cross-ply and angle-ply laminates and compared with finite element analysis results. As for the appropriate expression of the effective elastic stiffness matrix of the damaged ply, we verified four types of effective compliance/stiffness matrices including the Murakami, Yoshimura, Li and Maimí models. We found the Maimí model to be the most appropriate among these four models. Moreover, we successfully simplified the expressions for damage variables in the complicated infinite series obtained in our previous study. We also proved that this could contribute toward improving the accuracy of our analysis. After verifying the present model, the stress-strain response and failure strength of carbon- or glass- fiber-reinforced plastic cross-ply laminates were predicted using Maimí’s compliance model and the simplified damage variables.
Introduction

The application scope of advanced composite materials is increasing due to their superior mechanical properties like high specific modulus and strength. The specific modulus plays an important role in real structures, but the specific strength of these materials has not been effectively utilized in real applications owing to the incapability of failure analysis. The reason why effective designs considering the high specific strength are not yet developed is that structural designs are developed using the strain criterion based on initial ply failure. When load is applied to composite structures, matrix cracks are generated in the transverse ply. However, if the applied strain level is low, these cracks do not cause secondary damage and affect the reduction of stiffness. Furthermore, if the applied strain reaches a certain level, the damage migrates from the ply cracks, leading to catastrophic damage phenomena like delamination and fiber breakage. Thus, similar to metals, if designers consider the initial damage and users can predict the progress of the damage, the structural weight can be reduced. Therefore, damage tolerance designing is the next step for expanding the application scope of composite structures.

Designers need to analyze the stiffness reduction in composite structures owing to transverse cracks accurately. Transverse cracks occurring in cross-ply laminates have been studied since the 1970s.\textsuperscript{1–6} Initially, there were many stress analysis studies performed using the shear-lag model, which was developed to analyze the stress profile around discontinuous fibers.\textsuperscript{7} Using the shear-lag model, the damage progress could be predicted using the stress criterion and/or energy criterion. Specifically, the onset of transverse cracks from the viewpoint of micromechanics was analyzed. In the 1980s, the shear-lag model was improved.\textsuperscript{8,9} Finite element analysis (FEA)\textsuperscript{10} and the minimum energy principle model\textsuperscript{11–13} utilizing variation methods were proposed to analyze the stress field around the transverse cracks. These models enable us to calculate the stress field around the transverse cracks in cross-ply laminates very accurately.

In addition to the above approaches, continuous damage mechanics (CDM) models\textsuperscript{14–16} were developed simultaneously. CDM models are divided into the following two types: the first one involves the effective elastic stiffness or compliance matrix.

utilizing the damage tensor derived from the thermomechanical relationship; while the other one calculates the inelastic strain with internal state variables so that the average stress of the laminate can be estimated. Both models are fitted with the classical laminate theory (CLT) because the detailed stress distribution in the laminate is unnecessary and the damaged ply is homogenized. Therefore, arbitrary laminates other than cross-ply laminates can be analyzed easily. On the contrary, problems regarding the objective determination of damage tensor and internal state variables must be addressed.

In the 1990s, McCartney\textsuperscript{17} presented an accurate anisotropic elastic solution for cross-ply laminates, satisfying both the equilibrium and compatible equation. Pagano et al.\textsuperscript{18} proposed an accurate solution based on cylindrical bending. Moreover, several researchers analyzed the delamination migrating from the matrix crack from the viewpoint of energy balance.\textsuperscript{19,20} Xia et al.\textsuperscript{21} used the McCartney model to analyze damage progress in ceramic-matrix cross-ply laminates. Furthermore, using CDM, Gudmundson and Zang\textsuperscript{22} extended the two-dimensional model of Dvorak et al.\textsuperscript{23,24} which is applicable to an isotropic body, to obtain a three-dimensional model with the generalized laminate theory for analyzing three-dimensional laminates. As stated above, CDM can be applied to angle-ply laminates. Gudmundson and Zang applied the model to study stiffness reduction in angle-ply laminates. Kobayashi et al.\textsuperscript{25} used the Gudmundson and Zang model to predict the damage progress in quasi-isotropic carbon-fiber-reinforced plastic (CFRP) laminates. After the 2000s, several researchers\textsuperscript{26–28} continued to develop models for analyzing arbitrary laminates other than cross-ply laminates. However, the derived formulations are extremely complicated for ordinary people to use them easily.

Recently, we derived the analytical form of the damage tensor with transverse crack density by solving the Laplace equation for the displacement fields under the generalized plane strain condition.\textsuperscript{29} The laminate stiffness can be estimated with the obtained damage tensor through the CLT and CDM model proposed by Murakami and his colleagues.\textsuperscript{30,31} We have also proved that the estimated stiffness agrees with the finite element calculations and experimental results.\textsuperscript{14} This approach is extended to a three-dimensional model\textsuperscript{32} using a sophisticated model proposed by Li et al.\textsuperscript{33} However, the effective compliance matrix proposed by Murakami and his colleagues is asymmetric. This asymmetry of the compliance matrix was also observed in the study done by Lee et al.\textsuperscript{13} Furthermore, because the damage tensor is derived by solving the Laplace equation, it is written as a complicated infinite series.\textsuperscript{29}

The fiber breakage generally causes nonlinearity in the stress-strain curves when the applied strain is large. It is well known that Rosen\textsuperscript{34} originally studied the stress transfer length around fiber breaks as well as the unidirectional composite failure strength and applied to glass-epoxy monolayer specimens. Analytical models considering fiber breakage have been mainly developed in the field of ceramic matrix composites (CMCs) since the late 1980’s. This is because a stress concentration due to a fiber break can almost be neglected, so that the global load sharing model (GLS), wherein the load shed by a broken fiber is shared by all intact fibers, can be directly applied to the experiments. Curtin\textsuperscript{35} presents a famous theory to predict the ultimate tensile strength of the unidirectional composites assuming the GLS model. Neumeister\textsuperscript{36} developed an approximate solution of the stress-strain curve and strength of the composite, and
compared to a numerical result based on the fiber fragmentation theory formulated by Curtin. Hui et al. derived an explicit closed form solution of the evolution of fiber fragments and applied to estimate the strength of unidirectional composite materials. In general, the GLS models give a larger strength than the local load-sharing (LLS) model that considers local stress concentrations caused by fiber breaks. However, the GLS models are theoretically easy to handle. Therefore, it is suitable to utilize the GLS models to analytically formulate the damage tensor.

This study developed an appropriate expression for the effective stiffness matrix of damaged composite laminates and derived simplified expressions for the damage tensor with the fiber breakage and transverse crack density. Damage variable for fiber breakage was formulated using the GLS model for unidirectional fiber-reinforced composites. An approximate simplified expression for the damage tensor with transverse crack density was obtained from the Laplace equation, assuming the quadratic function. For validating the present model, the obtained damage tensor was substituted into CDM and CLT models, and the elastic constants of damaged composite laminates were then predicted for cross-ply and angle-ply laminates. As for the appropriate expression for the effective compliance/stiffness matrix of a damaged ply, we verified four types of damage matrices including the Murakami, Yoshimura, Li and Maimí models. We determined that the Maimí model was the most appropriate among these four models. Moreover, we succeeded in simplifying the expression for damage variables with complicated infinite series obtained in our previous study. We also proved that this could contribute toward the improving the analysis accuracy. Further, we determined the nonlinear stress-strain response and ultimate tensile strength of CFRP and glass-fiber-reinforced-plastic (GFRP) cross-ply laminates. We employed the Maimí model and simplified damage variables proposed in this study when calculating the stress-strain response. The ultimate tensile strength of CFRP cross-ply laminates was predicted based on a strain-based fiber failure criterion because fiber fracture in CFRP laminates often occurs at the point of laminate failure. For GFRP laminates, the stiffness reduction due to multiple-fiber fragmentation in 0° plies and the subsequent final laminate failure were determined using the GLS model.

**Model formulation**

*Effective elastic compliance/stiffness matrix of damaged ply*

Four models for the elastic compliance matrix of a damaged composite ply under the plane stress condition are introduced here and their characteristics are explained.

*Model 1: Murakami model* Murakami published a sophisticated book introducing CDM and proposed a compliance matrix for damaged composite plies with his
colleagues. They used the strain equivalent principle to obtain the following stress-strain relationship:

\[
\begin{pmatrix}
\varepsilon_{11} \\
\varepsilon_{22} \\
2\varepsilon_{12}
\end{pmatrix}
= 
\begin{pmatrix}
\frac{1}{(1-d_{11})E_1} & -\frac{\nu_{12}}{E_1} & 0 \\
-\frac{\nu_{12}}{E_1} & \frac{1}{(1-d_{22})E_2} & 0 \\
0 & 0 & \frac{1}{2} \left( \frac{1}{1-d_{11}} + \frac{1}{1-d_{22}} \right) \frac{1}{G_{12}}
\end{pmatrix}
\begin{pmatrix}
\sigma_{11} \\
\sigma_{22} \\
\sigma_{12}
\end{pmatrix}.
\]

(1)

\(E_i\) is the Young’s modulus, \(G_{ij}\) is the shear modulus, \(\nu_{ij}\) is the Poisson’s ratio, \(\varepsilon_{ij}\) is the strain tensor, \(\sigma_{ij}\) is the stress tensor, and \(d_{ij}\) is the damage variable. In Eq. (1), subscripts 1 and 2 denote the fiber direction and the in-plane transverse direction respectively. In our previous study, we found that this matrix is effective for obtaining the elastic constants of damaged composite laminates if the appropriate damage tensor is used. However, the compliance matrix in Eq. (1) is obviously asymmetric and this violates the existence of the strain energy function. Moreover, this form cannot be directly entered into the numerical simulation code as in FEA. As stated above, this asymmetry of the compliance matrix was also observed in the work of Lee.

Model 2: Yoshimura model Yoshimura et al. proposed the concept of the stress equivalent principle to overcome the difficulty of the asymmetry of the compliance matrix. The stress-strain relation can be written as:

\[
\begin{pmatrix}
\sigma_{11} \\
\sigma_{22} \\
\sigma_{12}
\end{pmatrix}
= 
\begin{pmatrix}
B_{11} & B_{12} & 0 \\
B_{21} & B_{22} & 0 \\
0 & 0 & B_{33}
\end{pmatrix}
\begin{pmatrix}
\varepsilon_{11} \\
\varepsilon_{22} \\
2\varepsilon_{12}
\end{pmatrix},
\]

(2)

where

\[
B_{11} = \frac{(1-d_{11})E_1}{1-\nu_{12}\nu_{21}} - \frac{d_{12}^2 \nu_{12}\nu_{21}(1+\nu_{23})E_1}{4 \Delta (1-\nu_{12}\nu_{21})},
\]

(3)

\[
B_{12} = \frac{1-d_{11}+d_{22}}{2} \frac{\nu_{12}E_2}{1-\nu_{12}\nu_{21}} - \frac{d_{11}d_{22} \nu_{12} (\nu_{23} + \nu_{12}\nu_{21}) E_2}{4 \Delta (1-\nu_{12}\nu_{21})},
\]

(4)

\[
B_{22} = \frac{1-d_{22}}{2} \frac{\nu_{12}E_2}{1-\nu_{12}\nu_{21}} - \frac{d_{22}^2 (\nu_{23} + \nu_{12}\nu_{21})^2 \nu_{21}}{4 \Delta (1+\nu_{23})(1-\nu_{12}\nu_{21})},
\]

(5)

\[
B_{33} = \frac{1-d_{11}+d_{22}}{2} G_{12},
\]

(6)

\[
\Delta = 1 - \nu_{23} - 2\nu_{12}\nu_{21}.
\]

(7)

In this case, the stiffness matrix is obviously symmetric. This effective stiffness matrix has already been inserted into the ABAQUS user subroutine to simulate the high-velocity impact problem. The simulation results roughly reproduced the damage progress observed experimentally, but the simulation underestimated the extent of damage compared to the experiments. Moreover, the degradation coefficient of shear modulus does not have any physical meaning. These points are discussed later when comparing the four models explained in this section.
Model 3: Li model  
Li et al.\textsuperscript{33} formulated the three-dimensional effective stiffness matrix for a ply with transverse cracking assuming a small damage. The two-dimensional effective stiffness matrix can be written as:

\[
\begin{pmatrix}
\sigma_{11} \\
\sigma_{22} \\
\sigma_{12}
\end{pmatrix} = \begin{pmatrix}
C_{11} - \frac{C_{23}^2}{C_{33}} & C_{12} - \frac{C_{13}C_{23}}{C_{33}} & 0 \\
C_{12} - \frac{C_{13}C_{23}}{C_{33}} & C_{22} - \frac{C_{13}^2}{C_{33}} & 0 \\
\text{sym.} & C_{66} & 0
\end{pmatrix}
\begin{pmatrix}
\varepsilon_{11} \\
\varepsilon_{22} \\
2\varepsilon_{12}
\end{pmatrix},
\]  

where

\[
C_{11} = \frac{1}{\Delta} E_1 - \omega \frac{E_1 \nu_{12} \nu_{21}}{\Delta^2},
\]

\[
C_{12} = \frac{\nu_{12}}{\Delta} E_2 - \omega \frac{E_2 \nu_{12}(1 - \nu_{12} \nu_{21})}{(1 + \nu_{23})\Delta^2},
\]

\[
C_{13} = \frac{\nu_{12}}{\Delta} E_2 - \omega \frac{E_2 \nu_{12}(\nu_{23} + \nu_{12} \nu_{21})}{(1 + \nu_{23})\Delta^2},
\]

\[
C_{22} = \frac{1}{(1 + \nu_{23})\Delta} E_2 - \omega \frac{E_2(1 - \nu_{12} \nu_{21})^2}{(1 + \nu_{23})^2 \Delta^2},
\]

\[
C_{23} = \frac{\nu_{23} + \nu_{12} \nu_{21}}{(1 + \nu_{23})\Delta} E_2 - \omega \frac{E_2(1 - \nu_{12} \nu_{21})(\nu_{23} + \nu_{12} \nu_{21})}{(1 + \nu_{23})^2 \Delta^2},
\]

\[
C_{33} = \frac{1}{(1 + \nu_{23})\Delta} E_2 - \omega \frac{E_2(\nu_{23} + \nu_{12} \nu_{21})^2}{(1 + \nu_{23})^2 \Delta^2},
\]

\[
C_{66} = G_{12} - \xi \omega G_{12}.
\]

Here, $\omega$ is the damage parameter related to tensile damage and $\xi$ is the constant damage parameter related to shear damage. $\omega$ and $\xi$ can be expressed as follows:\textsuperscript{32}

\[
\omega = 1 - \frac{E_2^d}{E_2} = d_{22},
\]

\[
\xi = \frac{1}{\omega} \left( 1 - \frac{G_{12}^d}{G_{12}} \right) \approx \frac{1}{\lambda}.
\]

Here, superscript $d$ denotes the property of the damaged ply and $\lambda$ is the material constant described later. Onodera and Okabe\textsuperscript{32} utilized this effective stiffness for predicting the stiffness reduction and steady-state cracking of laminates with ply cracking. The proposed CDM model agrees with the experimental and numerical results.\textsuperscript{32} However, the damage parameter $\omega$ and transverse crack density have upper limits because a small damage was assumed.

Model 4: Maimí model  
Maimí et al.\textsuperscript{41} proposed the complementary free energy function and thermodynamically derived the effective compliance matrix as follows:

\[
\begin{pmatrix}
\varepsilon_{11} \\
\varepsilon_{22} \\
2\varepsilon_{12}
\end{pmatrix} = \begin{pmatrix}
\frac{1}{(1-d_{11})E_1} & \frac{-\nu_{12}}{E_1} & 0 \\
\frac{1}{(1-d_{22})E_2} & 0 & 0 \\
\text{sym.} & \frac{1}{(1-d_{12})G_{12}} & \frac{1}{(1-d_{22})G_{22}}
\end{pmatrix}
\begin{pmatrix}
\sigma_{11} \\
\sigma_{22} \\
\sigma_{12}
\end{pmatrix}.
\]
The effective compliance matrix in this case is also explicitly symmetric. However, this case needs an additional damage variable $d_{12}$ for evaluating the shear stiffness reduction due to transverse cracks or fiber breaks. For the ply with transverse cracks, this parameter is derived from the displacement field of the damaged ply in this study. For the ply with fiber breaks, $d_{12}$ can be approximated as follows:

$$
\frac{1}{1 - d_{12}} = \frac{1}{2} \left( \frac{1}{1 - d_{11}} + 1 \right).
$$

(19)

The approximate relation of Eq. (19) was used when considering the ply with fiber breaks.

**Damage variables**

**Damage variable $d_{11}$ for multi-fiber fragmentation** An analytical expression for $d_{11}$ was developed by employing Curtin’s GLS model\(^{35}\) considering the ultimate tensile strength of unidirectional fiber-reinforced composites. Now, we consider the mechanical equilibrium on an arbitrary cross section in a unidirectional fiber-reinforced composite with broken fibers. Utilizing the shear-lag model, the slip length $l_f$ can be described as

$$
l_f = \frac{rT}{2\tau},
$$

(20)

where $T$ is the far-field axial fiber stress, $\tau$ is the fiber/matrix interfacial sliding stress, and $r$ is the fiber radius. If fiber breaks occur equally within the range $\pm l_f$, then the average stress carried by the broken fibers in the selected plane is half of that carried by the unbroken fibers. The stress carried by the broken and unbroken fibers in the selected plane can be described as

$$
\sigma_f = T\{1 - P_f(T, 2l_f)\} + \frac{T}{2} P_f(T, 2l_f).
$$

(21)

Here, the first term on the right-hand side represents the load carried by the unbroken fiber with the fraction $1 - P_f(T, 2l_f)$ and the second term is the average load carried by the broken fibers, whose fraction is $P_f(T, 2l_f)$. It is well known that the probability $P_f(T, 2l_f)$ of the fiber failure with applied stress $T$ and length $2l_f$ can be simplified as

$$
P_f(T, 2l_f) \approx \frac{2l_f}{L_0} \left( \frac{T}{\sigma_0} \right)^m = \left( \frac{T}{\sigma_c} \right)^{m+1} \quad \text{if} \quad \frac{2l_f}{L_0} \left( \frac{T}{\sigma_0} \right)^m \ll 1,
$$

(22)

where $m$ is the Weibull modulus and $\sigma_0$ is the mean strength at gauge length $L_0$. $\sigma_c$ is the characteristic strength defined as follows:

$$
\sigma_c = \left( \frac{\sigma_0 \tau L_0}{r} \right)^{1/(m+1)}.
$$

(23)
In the selected cross section, the following mechanical equilibrium condition must be satisfied:

\[ \sigma_1 = f \sigma_f, \]  

(24)

\( \sigma_1 \) is the stress applied on the unidirectional composite along the fiber direction and \( f \) is the fiber volume fraction. Using the Voigt model for representing the Young’s modulus of composite, the unidirectional axial composite stress \( \sigma_1 \), axial fiber stress \( T \), and unidirectional Yong’s modulus \( E_1 \) are expressed as

\[ \sigma_1 = (1 - d_{11}) E_1 \varepsilon_1, \]  

(25)

\[ T = E_f \varepsilon_1, \]  

(26)

\[ E_1 = f E_f + (1 - f) E_m \approx f E_f. \]  

(27)

Here, \( \varepsilon_1 \) is the unidirectional composite strain, \( E_f \) is the fiber axial modulus, and \( E_m \) is the matrix modulus. We neglected the term \((1 - f) E_m\) in Eq. (27) because \( E_f \gg E_m \) is approximately satisfied in the case of polymer matrix composites. Using Eqs. (21), (22) and (25) - (27) in Eq. (24), the damage variable was simply derived as

\[ d_{11} = \frac{1}{2} \left( \frac{T}{\sigma_c} \right)^{m+1}. \]  

(28)

The remaining unknown variable is the far-field fiber axial stress \( T \). Substituting Eqs. (21) and (22) into Eq. (24), the following nonlinear equation for \( T \) was obtained.

\[ \sigma_1 = f T \left( 1 - \frac{1}{2} \left( \frac{T}{\sigma_c} \right)^{m+1} \right) \]  

(29)

Stress \( T \) at applied load \( \sigma_1 \) was numerically obtained by solving the above nonlinear equation. When a cross-ply laminate having \( 0^\circ \) plies with volume fraction \( V_1 \) and the \( 90^\circ \) plies with volume fraction \( V_2 \) is considered, the applied axial laminate stress \( \sigma_L \) can be described using the rule of mixture as follows:

\[ \sigma_L = V_1 \sigma_1 + V_2 \sigma_2 \approx V_1 \sigma_1, \]  

(30)

\( \sigma_1 \) is the \( 0^\circ \) ply stress and \( \sigma_2 \) is the \( 90^\circ \) ply stress. We decided to neglect the second term on the right-hand side in Eq. (30). This is because fiber breaks in the \( 0^\circ \) ply may start after the saturation of transverse cracks and the \( 90^\circ \) plies have very small load-bearing capacity during saturation of transverse cracks. Using Eq. (30) in Eq. (29), the nonlinear expression for stress \( T \) is rewritten as

\[ \frac{\sigma_L}{V_1} = f T \left( 1 - \frac{1}{2} \left( \frac{T}{\sigma_c} \right)^{m+1} \right). \]  

(31)
The ultimate tensile strength of cross-ply laminates can be derived using Eq. (31). The ultimate failure condition of composite laminates is described by the following equation:

\[
\frac{d\sigma_L}{dT} = 0. \tag{32}
\]

The maximum far-field fiber stress \( T_{\text{max}} \) and ultimate tensile strength \( \sigma_{\text{ULT}}^L \) of cross-ply laminates were simply obtained by substituting Eq. (31) into Eq. (32).

\[
T_{\text{max}} = \left( \frac{2}{m + 2} \right)^{1/(m+1)} \sigma_c \tag{33}
\]

\[
\sigma_{\text{ULT}}^L = V_1 f \sigma_c \left( \frac{2}{m + 2} \right)^{1/(m+1)} \frac{m + 1}{m + 2} \tag{34}
\]

The maximum value of damage variable \( d_{11} \) was obtained using Eq. (33) in Eq. (28).

\[
d_{11}^{\text{max}} = \frac{1}{m + 2} \tag{35}
\]

\( d_{11} \) increased to its maximum value in Eq. (35) under the ultimate tensile failure condition. In this study, the far-field stress \( T \) was calculated using the Newton method to solve the nonlinear equation (Eq. (31)) at a given laminate tensile stress \( \sigma_L \) until the ultimate tensile failure condition in Eq. (32) was satisfied. \( d_{11} \) was obtained using the calculated stress \( T \) in Eq. (28).

**Damage variable \( d_{22} \) associated with transverse cracking** In any of the effective stiffness/compliance models stated above, \( d_{22} \) is necessary to evaluate the compliance/stiffness matrix of the damaged ply. The governing equation (i.e., Laplace equation) of the corresponding problem was derived. The simplified solution of the equation obtained assuming that the displacement field in the longitudinal direction can be expressed as a quadric function. Further, the boundary condition for the governing equation was loosened.

As shown in Fig. 1, the solved problem is the displacement field for the damaged transverse ply including periodic matrix cracks having an interval of \( 2l \). These matrix cracks fully propagate in the \( z \) direction and reach the interface. The longitudinal strain of the neighboring ply is assumed to be uniform and unaffected by these cracks. Considering the symmetry of the problem, only the first quadrant in the \( xy \) plane was addressed. The plane strain condition was assumed, and the constitutive relations are given by

\[
\varepsilon_{xx}(x, y) = \frac{\partial u(x, y)}{\partial x} = C_1 \sigma_{xx}(x, y) - C_2 \sigma_{yy}(x, y), \tag{36}
\]

\[
\varepsilon_{yy}(x, y) = \frac{\partial v(x, y)}{\partial y} = C_1 \sigma_{yy}(x, y) - C_2 \sigma_{xx}(x, y), \tag{37}
\]

\[
\gamma_{xy}(x, y) = \frac{\sigma_{xy}(x, y)}{G_{23}} = \frac{\partial v(x, y)}{\partial x} + \frac{\partial u(x, y)}{\partial y} \approx \frac{\partial v(x, y)}{\partial x}. \tag{38}
\]
Figure 1. Representative volume element in a cracked ply with transverse crack spacing $2l$ and ply thickness $2t$. $(1, 2, 3)$ is the material coordinate system, and $(x, y, z)$ is the representative volume element coordinate system.

Here, $u$ and $v$ are the displacements along the $x$ and $y$ directions respectively. $C_1$ and $C_2$ are given by

$$C_1 = \frac{1 - \nu_{12}\nu_{21}}{E_2}, \quad C_2 = \frac{\nu_{23} + \nu_{12}\nu_{21}}{E_2}. \quad (39)$$

We assumed that $\partial u / \partial y$ was negligible in Eq. (38) so that the compatible condition of the strain tensor was not satisfied. To obtain the governing equation for displacement $v$, the following relationship was introduced:

$$\varepsilon_{xx}(x, y) = a\varepsilon_{yy}(x, y), \quad (40)$$

where $a$ is the effective Poisson’s ratio derived from the equilibrium equation. Substituting Eq. (40) into Eqs. (36) and (37), we obtained the stress with displacement $v$ as follows:

$$\sigma_{xx}(x, y) = \frac{aC_1 + C_2}{C_1^2 - C_2^2} \frac{\partial v(x, y)}{\partial y}, \quad (41)$$

$$\sigma_{yy}(x, y) = \frac{C_1 + aC_2}{C_1^2 - C_2^2} \frac{\partial v(x, y)}{\partial y}. \quad (42)$$

These stresses satisfy the following two-dimensional equilibrium equations:

$$\frac{\partial \sigma_{xx}}{\partial x} + \frac{\partial \sigma_{xy}}{\partial y} = 0, \quad (43)$$

$$\frac{\partial \sigma_{xy}}{\partial x} + \frac{\partial \sigma_{yy}}{\partial y} = 0. \quad (44)$$
Substituting Eqs. (38) and (41) into Eqs. (43) and removing the trivial case (i.e., $\partial^2 v / \partial x \partial y \neq 0$), $a$ was calculated as

$$a = -\frac{C_2 + G_{23}(C_1^2 - C_2^2)}{C_1} \quad (45)$$

$$a = -\frac{E_2(\nu_{23} + \nu_{12}\nu_{21}) + G_{23}\{(1 - \nu_{12}\nu_{21})^2 - (\nu_{23} + \nu_{12}\nu_{21})^2\}}{E_2(1 - \nu_{12}\nu_{21})}. \quad (45)$$

Furthermore, substituting Eqs. (38) and (42) into Eq. (44), the following governing equation of the displacement field was obtained:

$$\frac{\partial^2 v}{\partial x^2} + \lambda^2 \frac{\partial^2 v}{\partial y^2} = 0, \quad (46)$$

where

$$\lambda = \sqrt{\frac{C_1 + aC_2}{G_{23}(C_1^2 - C_2^2)}} = \sqrt{\frac{E_2 - G_{23}(\nu_{23} + \nu_{12}\nu_{21})}{G_{23}(1 - \nu_{12}\nu_{21})}}. \quad (47)$$

The boundary condition of the governing equation is written as

$$\begin{align*}
\sigma_{xy}(0, y) &= 0 \iff \frac{\partial v}{\partial x}(0, y) = 0, \quad (48) \\
v(t, y) &= \varepsilon_{yy}^{\infty}, \quad (49) \\
v(x, 0) &= 0, \quad (50) \\
\sigma_{yy}(x, l) &= 0 \iff \frac{\partial v}{\partial y}(x, l) = 0, \quad (51)
\end{align*}$$

where $\varepsilon_{yy}^{\infty}$ is the applied strain of the ply parallel to the $y$-axis and $2t$ is the ply thickness. The displacement field can be solved with Eq. (46). In our previous study, this partial differential equation was solved by the variable separation method. However, the obtained solution was an infinite series and very complicated. Therefore, this study obtained a simplified form of the displacement field.

To obtain the simplified solution, the displacement form of the following type was assumed:

$$v(x, y) = A(y) x^2 + B(y) x + C(y). \quad (52)$$

Using the displacement in Eq. (52) in Eqs. (48) and (49) yielded

$$B(y) = 0, \quad (53)$$

$$C(y) = \varepsilon_{yy}^{\infty} y - A(y) t^2. \quad (54)$$

Thus, Eq. (52) can be written as

$$v(x, y) = A(y)(x^2 - t^2) + \varepsilon_{yy}^{\infty} y. \quad (55)$$
Next, our main task was to explicitly determine $A(y)$. The boundary condition of Eq. (50) gives

$$A(0) = 0. \quad (56)$$

However, it is impossible to satisfy the boundary condition of Eq. (51) exactly as it is. Thus, according to McCartney,\textsuperscript{17} the following averaged boundary condition was used:

$$\frac{1}{t} \int_0^t \partial v(x, l) \frac{\partial}{\partial y} dx = 0. \quad (57)$$

Hence, using Eq. (55) into Eq. (57) results in

$$\frac{dA(l)}{dy} = \frac{3\varepsilon_{yy}}{2t^2}. \quad (58)$$

Similar to Eq. (51), the government equation, i.e., Eq. (46), cannot be solved directly. Instead of Eq. (46), the following averaged government equation was here solved.

$$\frac{1}{t} \int_0^t \left( \frac{\partial^2 v}{\partial x^2} + \lambda^2 \frac{\partial^2 v}{\partial y^2} \right) dx = 0 \quad (59)$$

Using Eq. (55) in Eq. (59) yielded the following ordinary differential equation

$$\frac{d^2 A(y)}{dy^2} - \beta^2 A(y) = 0, \quad (60)$$

where

$$\beta = \frac{\sqrt{3}}{\lambda t}. \quad (61)$$

The solution of Eq. (60) with the boundary conditions in Eqs. (56) and (58) is

$$A(y) = \frac{3\varepsilon_{yy}}{2t^2 \beta} \sinh \beta y \cosh \beta l. \quad (62)$$

Thus, it can be shown that

$$v(x, y) = \frac{3\varepsilon_{yy}}{2t^2 \beta} \sinh \beta y \cosh \beta l (x^2 - t^2) + \varepsilon_{yy} y. \quad (63)$$

As stated in our previous paper,\textsuperscript{29} the damage variable is the ratio of the inelastic strain due to crack opening to the total strain and is finally given by

$$d_{22} = \frac{\varepsilon_{yy}}{\varepsilon_{yy}} - \frac{1}{lt} \int_0^t v(x, l) dx = \tanh \beta l = \frac{2\rho}{\beta \tanh \frac{\beta}{2\rho}}. \quad (64)$$
where $\rho = 1/(2l)$ is the transverse crack density in the damaged ply. As stated above, we derived the following equation:\textsuperscript{29}

$$d_{22} = 1 - \frac{8}{\pi^3 \lambda t} \sum_{n=1}^{\infty} \frac{1}{(2n-1)^3} \frac{\tanh[(2n-1)\pi \lambda t \rho]}{\rho}.$$  \hspace{1cm} (65)

Equation (64) is obviously simpler than Eq. (65) and loosening the boundary condition Eq. (51) increases crack opening, so that Eq. (64) gives better predictions than Eq. (65) in some cases. We will describe this section later through verifications and validations.

**Damage variable $d_{12}$ associated with transverse cracking** When the effective compliance matrix shown in Eq. (18) is used, the analytical form for damage variable $d_{12}$ is required. The schematic shown in Fig. 1 is also considered here. The neighboring ply deforms under a constant shear strain $\gamma_{yz}^\infty$ in the $yz$ plane and the displacement field is assumed as

\begin{align*}
  u(x, y, z) &= v(x, y, z) = 0, \\
  w &= w(x, y).
\end{align*}  \hspace{1cm} (66) (67)

Thus, these equations give $\sigma_x = \sigma_y = \sigma_z = \sigma_{xy} = 0$ and $\varepsilon_x = \varepsilon_y = \varepsilon_z = \gamma_{xy} = 0$, so that the out of plane shear stresses are nonzero and given as

\begin{align*}
  \sigma_{xz}(x, y) &= G_{12} \gamma_{xz}(x, y) = G_{12} \frac{\partial w(x, y)}{\partial x}, \\
  \sigma_{yz}(x, y) &= G_{12} \gamma_{yz}(x, y) = G_{12} \frac{\partial w(x, y)}{\partial y}.
\end{align*}  \hspace{1cm} (68) (69)

The stresses should satisfy the following three-dimensional equilibrium equations:

\begin{align*}
  \frac{\partial \sigma_{xx}}{\partial x} + \frac{\partial \sigma_{xy}}{\partial y} + \frac{\partial \sigma_{xz}}{\partial z} &= 0, \\
  \frac{\partial \sigma_{xy}}{\partial x} + \frac{\partial \sigma_{yy}}{\partial y} + \frac{\partial \sigma_{yz}}{\partial z} &= 0, \\
  \frac{\partial \sigma_{xz}}{\partial x} + \frac{\partial \sigma_{yz}}{\partial y} + \frac{\partial \sigma_{zz}}{\partial z} &= 0.
\end{align*}  \hspace{1cm} (70) (71) (72)

These stresses given in Eqs. (68) and (69) automatically satisfy Eqs. (70) and (71) and leads to the following governing equation derived from Eq. (72):

$$\frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 w}{\partial y^2} = 0.$$  \hspace{1cm} (73)
As mentioned in the previous section, the following boundary conditions should be satisfied:

\[
\sigma_{xz}(0, y) = 0 \iff \frac{\partial w}{\partial x}(0, y) = 0, \tag{74}
\]

\[
w(t, y) = \gamma_{yz}^\infty y, \tag{75}
\]

\[
w(x, 0) = 0, \tag{76}
\]

\[
\sigma_{yz}(x, l) = 0 \iff \frac{\partial w}{\partial y}(x, l) = 0. \tag{77}
\]

This boundary problem defined by Eqs. (73)-(77) is almost the same as the one defined by Eqs. (46)-(51); therefore, the same derivation procedure can be adopted for this boundary problem. Thus, the displacement field is given by

\[
w(x, y) = \frac{3\gamma_{yz}^\infty}{2t^2\beta_{12}} \sinh \beta_{12} y (x^2 - t^2) + \gamma_{yz}^\infty y, \tag{78}
\]

\[
\beta_{12} = \sqrt{\frac{3}{t}}. \tag{79}
\]

The shear damage variable \(d_{12}\) can be defined as

\[
d_{12} = 1 - \frac{G_d^{12}}{G_{12}}, \tag{80}
\]

where \(G_{12}^{d}\) is the shear stiffness of the ply with transverse cracking. The average ply shear strain \(\gamma_{yz}^{ave}\) not considering the crack-opening displacement and applied shear strain \(\gamma_{yz}^\infty\) are described as follows:

\[
\gamma_{yz}^{ave} = 1 - \frac{\sigma_{yz}}{G_{12}}, \tag{81}
\]

\[
\gamma_{yz}^\infty = 1 - \frac{\sigma_{yz}}{G_d^{12}}. \tag{82}
\]

Substituting Eqs. (81) and (82) into Eq. (80), \(d_{12}\) can be rewritten as

\[
d_{12} = 1 - \frac{\gamma_{yz}^{ave}}{\gamma_{yz}^\infty}. \tag{83}
\]

The average shear strain is defined by

\[
\gamma_{yz}^{ave} = \frac{1}{lt} \int_0^t w(x, l) dx. \tag{84}
\]

We obtained \(d_{12}\) from Eqs. (78), (83), and (84).

\[
d_{12} = \frac{\gamma_{yz}^\infty - \frac{1}{lt} \int_0^t w(x, l) dx}{\gamma_{yz}^\infty} = \frac{\tanh \beta_{12} l}{\beta_{12} l} = \frac{2\rho}{\beta_{12} \tanh \beta_{12}} \frac{2\rho}{2\rho}. \tag{85}
\]
The reduction in shear modulus was initially determined by Hashin,\textsuperscript{11} by using the variation approach. Recently, Onodera and Okabe\textsuperscript{32} also obtained the shear damage variable with an infinite series.

\begin{equation}
    d_{12} = 1 - \frac{8}{\pi^3 t} \sum_{n=1}^{\infty} \frac{1}{(2n - 1)^3} \tanh[(2n - 1)\pi t \rho] \rho
\end{equation}

However, Eq. (85) is obviously simpler than the infinite series of Eq. (86).

**Effective elastic constants for the damaged composite laminates**

The substitution of damage variables $d_{22}$ and $d_{12}$ into Eqs. (1), (2), (8), and (18) gives the effective compliance/stiffness matrix of a ply with transverse cracks as a function of crack density $\rho$, and fiber breaks can be considered by substituting $d_{11}$ into Eqs. (1), (2), and (18). The effective stiffness of composite laminates with transverse cracks can be estimated through the CLT using the effective compliance matrix of a damaged ply.

Let us consider the coordinate systems shown in Fig. 2. The effective compliance matrix and thermal expansion coefficient of the $k$th ply having transverse crack density $\rho$ in material coordinate system $(1, 2, 3)$ are defined as $\bar{C}_k(\rho)$ and $\bar{\alpha}_k$, respectively. Similarly, those of laminate coordinate system $(X, Y, Z)$ are defined as $\bar{C}_k(\rho)$ and $\bar{\alpha}_k$, respectively. When the fiber angle is given by $\theta_k$, $\bar{C}_k(\rho)$ and $\bar{\alpha}_k$ are given as

\begin{equation}
    \bar{C}_k(\rho) = R_k C_k(\rho) T_k^{-1}, \tag{87}
\end{equation}

\begin{equation}
    \bar{\alpha}_k = R \alpha_k, \tag{88}
\end{equation}

where

\begin{equation}
    \alpha_k = \begin{bmatrix} \alpha_{11} & \alpha_{22} & 0 \end{bmatrix}^T, \tag{89}
\end{equation}

\begin{equation}
    R_k = \begin{bmatrix} \cos^2 \theta_k & \sin^2 \theta_k & -\sin \theta_k \cos \theta_k \\
    \sin^2 \theta_k & \cos^2 \theta_k & \sin \theta_k \cos \theta_k \\
    2 \sin \theta_k \cos \theta_k & -2 \sin \theta_k \cos \theta_k & \cos^2 \theta_k - \sin^2 \theta_k \end{bmatrix}, \tag{90}
\end{equation}

\begin{figure}[h]
\centering
\includegraphics[width=0.4\textwidth]{figure2.png}
\caption{Relationship between the laminate coordinate system $(X, Y, Z)$ and material coordinate system $(1, 2, 3)$.}
\end{figure}
\[ T_k = \begin{bmatrix} \cos^2 \theta_k & \sin \theta_k \cos \theta_k & -2 \sin \theta_k \cos \theta_k \\ \sin \theta_k \cos \theta_k & \cos^2 \theta_k & 2 \sin \theta_k \cos \theta_k \\ \sin \theta_k \cos \theta_k & -\sin \theta_k \cos \theta_k & \cos^2 \theta_k - \sin^2 \theta_k \end{bmatrix}. \]  \hspace{1cm} (91)

\( \alpha \) is the thermal expansion coefficient. Therefore, according to the CLT, the effective laminate strain \( \varepsilon_L \) is expressed as

\[ \varepsilon_L = C_L \sigma_L + \alpha_L \Delta T, \]  \hspace{1cm} (92)

where the effective stiffness matrix \( C_L(\rho) \) and thermal expansion coefficient \( \alpha_L(\rho) \) of the cracked laminate can be written as

\[ C_L(\rho) = [C_{Lij}] = \left[ \frac{1}{t_L} \sum_{k=1}^{N} t_k C^{-1}_{k}(\rho) \right]^{-1}, \]  \hspace{1cm} (93)

\[ \alpha_L(\rho) = [\alpha_{Li}] = C_L \left[ \frac{1}{t_L} \sum_{k=1}^{N} t_k \alpha^{-1}_{k}(\rho) \alpha_k \right]. \]  \hspace{1cm} (94)

\( \sigma_L \) is the applied axial laminate stress, \( t_L \) is the thickness of the corresponding composite laminates, and \( \Delta T (= T - T_{sf}) \) is the difference between the testing temperature \( T \) and stress-free temperature \( T_{sf} \). Therefore, the effective elastic constants and effective thermal expansion coefficients of the laminates are given as

\[ E_X = \frac{1}{C_{11}(\rho)}, \quad E_Y = \frac{1}{C_{22}(\rho)}, \quad \nu_{XY} = -\frac{C_{12}(\rho)}{C_{11}(\rho)}, \quad G_{XY} = \frac{1}{C_{66}(\rho)}, \]  \hspace{1cm} (95)

\[ \alpha_X = \alpha_{L1}(\rho), \quad \alpha_Y = \alpha_{L2}(\rho). \]  \hspace{1cm} (96)

We can derive the effective elastic constants analytically with the crack density and fiber breaks through the CLT. The stress-strain relationship of damaged laminates can be obtained using Eq. (92).

**Results and Discussions**

**Verification of damage models**

The stiffness reduction in laminates with transverse cracking was studied using five approaches for verifying the effective compliance/stiffness matrices and proposed damage variables \( d_{22} \) and \( d_{12} \). Murakami\_simplified shows the Murakami model using \( d_{22} \) expressed in a simplified form in Eq. (64). Yoshimura\_simplified is the Yoshimura model with \( d_{22} \) expressed in a simplified form, identical to Murakami\_simplified. Li\_simplified is the Li model including the damage parameter \( \omega \) in Eqs. (16) and (64), and constant damage parameter \( \xi \) in Eqs. (17) and (47). Maimí\_simplified gives the Maimí model with simplified forms of \( d_{22} \) in Eq. (64) and \( d_{12} \) in Eq. (85). Maimí\_infinite\_series describes the result of the Maimí model with infinite forms of \( d_{22} \) in Eq. (65) and \( d_{12} \) in Eq. (86). In Li\_simplified, the upper limit of the transverse crack density resulting
from the assumption of a small damage postulated in Li’s effective stiffness matrix was determined in the same manner as in our previous study. Table 1 presents the upper limit of the transverse crack density in GFRP laminates used in Li_simplified.

For verification, comparisons to results obtained using FEA are presented for [90/0]s, GFRP cross-ply laminates. The material properties listed in Table 2 were used. Transverse cracks are assumed to exist in the 90° plies and face the outer surface. Gudmundson and Zang calculated the reduction in Poisson’s ratio and Young’s modulus due to the increase in the transverse crack density. When the matrix crack faces the surface, the crack length should be doubled to include the surficial effect and satisfy the boundary condition. Therefore, we obtain

\[
d_{22} = \frac{4\rho}{\beta} \tanh \left( \frac{\beta}{4\rho} \right),
\]  
(97)  
\[
d_{12} = \frac{4\rho}{\beta_{12}} \tanh \left( \frac{\beta_{12}}{4\rho} \right),
\]  
(98)  
\[
d_{22} = 1 - \frac{4}{\pi^3 \lambda t} \sum_{n=1}^{\infty} \frac{1}{(2n-1)^3} \frac{\tanh[2(2n-1)\pi \lambda t \rho]}{\rho},
\]  
(99)  
\[
d_{12} = 1 - \frac{4}{\pi^3 \lambda t} \sum_{n=1}^{\infty} \frac{1}{(2n-1)^3} \frac{\tanh[2(2n-1)\pi \lambda t \rho]}{\rho}.
\]  
(100)

The comparison results are shown in Figs. 3 and 5. As for Young’s modulus, all approaches reproduce the tendency of the results observed in FEA. When comparing Maimí_simplified and Maimí_infinite series, it is shown that the simple forms of Eqs. (64) and (85) yielded results closer to the FEA results than the infinite series forms of Eqs. (65) and (86). Thus, Eqs. (65) and (86) gave smaller crack openings than the FEA results and loosening the boundary condition may improve the tendency of the crack opening displacement to match with those obtained using FEA. Murakami_simplified, Li_simplified, Maimí_simplified and Maimí_infinite series captured the degradation tendency of the Poisson’s ratio; however, Yoshimura_simplified

**Figure 4.** Comparison of Poisson’s ratio reduction in GFRP [90/0]_s due to transverse cracking predicted using present models and FEA (Gudmundson and Zhang^{22}).

obviously underestimated the degradation. This causes the significant errors in the case of angle-ply laminates because the non-diagonal component directly affects the Young’s modulus of the laminate.

Gudmundson and Zhang^{22} also calculated the stiffness reduction in several types of angle-ply laminates using FEA. The present model was verified by comparison with the results for \([\pm55]_N\) angle-ply GFRP laminates. The material properties listed in Table...

2 were used. Figures 5 - 10 show the changes in the Young’s moduli, shear modulus, Poisson’s ratio, and thermal expansion coefficients of [±55]_N laminate as a function of the transverse crack density. Clearly, Maimí_simplified shows the best agreement among these five approaches for any of the elastic constants, whereas Yoshimura_simplified cannot capture the trends of Young’s modulus and Poisson’s ratio at all. As stated above,
Figure 7. Comparison of shear modulus reduction in GFRP \([\pm 55]_N\) laminate due to transverse cracking predicted by present models and FEA (Gudmundson and Zhang\textsuperscript{22}).

Figure 8. Comparison of Poisson’s ratio change in GFRP \([\pm 55]_N\) laminate due to transverse cracking predicted by present models and FEA (Gudmundson and Zhang\textsuperscript{22}).

Poisson’s ratio is a critical parameter for evaluating the properties of angle-ply laminates as it reflects the behavior of non-diagonal components in compliance/stiffness matrix. The trends of Yoshimura\_simplified are substantially different from those observed in FEA. Therefore, we do not recommend using Yoshimura\_simplified for evaluating angle-ply laminates.
Figure 9. Comparison of axial laminate thermal expansion coefficient reduction in GFRP \([\pm 55]_N\) due to transverse cracking predicted by present models and FEA (Gudmundson and Zhang\textsuperscript{22}).

Although the results obtained using all the models agree well with the FEA results, Maimí\_simplified shows the best agreement. In fact, we proved that Maimí\_simplified is the most appropriate approach among five approaches considering in this study.
Nonlinear stress-strain response of CFRP cross-ply laminates

The nonlinear stress-strain response of CFRP cross-ply laminates resulting from transverse cracking was calculated using the present model and compared to the experimental results obtained in this study. We also applied our model to the results reported by Fikry et al.\textsuperscript{42} The stress-strain response of cross-ply laminates with transverse cracking was calculated using Eqs. (92)-(94). From the verification result described in the previous section, the effective stiffness model of Maimí simplified composed of the Maimí model with simplified forms of $d_{22}$ in Eq. (64) and $d_{12}$ in Eq. (85) was utilized to predict the stiffness reduction due to transverse cracks in 90$^\circ$ plies. In CFRP laminates subjected to quasi-static monotonic tensile loading, fiber fracture often occurs at the ultimate failure stress of the laminate. Therefore, the stiffness reduction owing to fiber breaks was not considered here, and the ultimate tensile strength of CFRP cross-ply laminates was predicted based on a strain-based fiber failure criterion presented by McCartney\textsuperscript{27} to determine the fracture point in the nonlinear stress-strain curve. In this criterion, the calculated effective laminate axial strain using Eq. (92) is considered equal to the fiber axial strain in 0$^\circ$ plies. When the effective laminate axial strain is equal to the critical strain, $\varepsilon_{fc}$, during ultimate fiber failure, ultimate failure of the laminate occurs. The ultimate fiber failure strain, $\varepsilon_{fc}$, is derived from the spring element model (SEM) simulation,\textsuperscript{43} which considers the surficial stress concentration obtained from multiple-fiber fragmentation tests.\textsuperscript{44} The bimodal Weibull distribution was applied to reproduce the statistically distributed strength in fibers. A stress concentration factor of 1.9 was used. The average ultimate fiber failure strain obtained by 100 SEM simulations scaled with each specimen size, was regarded as the ultimate fiber failure strain $\varepsilon_{fc}$. Table 3 lists the material properties of the T700S and resin and Table 4 shows bimodal Weibull parameters of the T700S fiber used in SEM simulations. The evolution of transverse crack density $\rho$ as a function of the applied laminate stress is needed to predict the nonlinear stress-strain curves of the laminates. In this study, to validate the proposed stiffness reduction model, we assumed the following Weibull form for transverse crack density evolution:

$$\rho = \rho_s \left[ 1 - \exp \left\{ - \left( \frac{\sigma_L - \sigma_{L0}}{\sigma_{Lc}} \right)^{m_T} \right\} \right],$$

where \( \rho_s \) is the saturated transverse crack density, \( \sigma_{L0} \) is the initiation stress of the transverse crack, \( \sigma_{Le} \) is the Weibull scale parameter, and \( m_T \) is the Weibull modulus. These parameters were determined by fitting with the experimental results.

We performed the experiments by ourselves to validate our model presented in this study. Here, we briefly explain the experimental procedures followed to determine the stiffness reduction, transverse crack density, and stress-strain curves of the cross-ply laminates. Loading and unloading tests were conducted to obtain the nonlinear stress-strain response of cross-ply laminates, transverse crack density in 90\(^\circ\) plies, and stiffness reduction. The [0/90\(_s\)/0\(_l\)] cross-ply laminate was composed of T700S/2592 (Toray Industries) unidirectional plies. The laminate specimen had a length, width, and thickness of 249, 25, and 1.42 mm, respectively. A strain gauge (Kyowa Electronic Instruments Co.) was used to measure the strain in the laminate. The free edge of the laminate was polished by a diamond grinding disk (Buehler Ltd.) to observe the transverse crack density. Loading and unloading tests were performed using a servo-hydraulic testing machine MTS810 (MTS Systems Corporation) and involved the following steps. (1) The specimen was loaded with a crosshead speed 1.0 mm/min. (2) When the load reached a specific value, the specimen was held at this load and the transverse cracks were observed at the free edge of the specimen using RepliSet (Struers). (3) The specimen was then unloaded with a crosshead speed 1.0 mm/min until the load reached zero. This loading/unloading cycle comprising steps (1)-(3) was repeated until the specimen failed.

The stress-strain relationship for the T700S/2592 [0/90\(_s\)/0\(_l\)] laminate predicted from the present model was compared to the obtained experiment results. We denote T700S/2592 as CFRP-I. The material properties of the ply, parameters of transverse crack evolution, and ultimate fiber failure strain, \( \varepsilon_{fc} \), derived from SEM simulations are listed in Tables 5, 6, and 7, respectively. The out-of-plane shear modulus, \( G_{23} \), of CFRP-I ply given in Table 5 was derived as follows:

\[
G_{23} = \frac{E_2}{2(1 + \nu_{23})}. \tag{102}
\]

Parameters of transverse crack density evolution were determined by fitting the calculated results of the present model with the experimental data as shown in Fig. 11 (a). Figure 11 (b) presents a comparison of the predicted results for stiffness reduction as a function of transverse crack density determined by using the present model with experimental results. The results predicted using the present model agree quantitatively with the experimental results obtained through loading/unloading tests. The predicted stress-strain responses of the T700S/2592 [0/90\(_s\)/0\(_l\)] laminate was compared to the experimental results, as shown in Fig. 11 (c). The results of the present model obtained considering stiffness reduction due to transverse cracking show good agreement with the experimental data. According to these results, the nonlinearity of the stress-strain responses observed in the 200-350 MPa range is mainly due to transverse cracking. The ultimate failure stress and strain determined from the critical-strain-based criterion also agree with the experimental data. This result implies that the ultimate failure strength of CFRP laminates with 0\(^\circ\) plies can be determined using the strain-based fiber criterion,

and the ultimate fiber failure strain used in this criterion can be predicted through SEM simulations.

The nonlinear stress-strain behavior of the T700SC/2592 [0/90/8/0] laminate was predicted using the present model and the results were compared to the experimental result obtained by Fikry et al. $^{42}$ We denote T700SC/2592 as CFRP-II. The material properties of the ply, parameters of transverse crack evolution, and ultimate fiber failure strain, $\varepsilon_{fc}$, derived from SEM simulations are also listed in Table 5, 6, and 7, respectively. The out-of-plane shear modulus $G_{23}$ of CFRP-II ply given in Table 5 was estimated using Eq. (102). The fiber volume fraction, $f$, of CFRP-II is estimated as

$$f = \frac{E_1 - E_m}{E_f - E_m}, \quad (103)$$
Figure 11. Comparison of results predicted using present model for (a) transverse crack density evolution, (b) stiffness reduction, and (c) stress-strain response of T700S/2592 [0/90°] laminate with experimental results.

where $E_f$ is the fiber axial Young’s modulus and $E_m$ is the matrix Young’s modulus given in Table 3. The crack evolution parameters used in Eq. (101) were derived by fitting the predicted results with the experiment results, as shown in Fig. 12 (a). The predicted results for stiffness reduction as a function of the transverse crack density show excellent agreement with the experimental results, as shown in Fig. 12 (b). Figure 12 (c) presents the nonlinear stress as a function of the longitudinal or transverse strain obtained using the present model and through experiments. The present model considering the stiffness reduction due to transverse cracks can predict the nonlinearity of the stress-strain response up to the ultimate failure strength of the laminate estimated using the critical-strain-based criterion.

Nonlinear stress-strain response of GFRP cross-ply laminates

The nonlinear stress-strain behavior of E-glass/TX24235 GFRP [0/90°]$_n$ ($n = 2, 4, 6$) laminates was predicted to validate our proposed damage variables $d_{11}$, $d_{22}$, and $d_{12}$. The stress-strain responses of cross-ply laminates with transverse cracking and fiber breaks were calculated using Eqs. (92)-(94). The effective stiffness model Maimi simplified comprising of the Maimi model with simplified forms of $d_{22}$ in Eq. (64) and $d_{12}$ in Eq. (85) was utilized to predict the stiffness reduction due to transverse cracks in 90° plies. In
the case of GFRP laminates, the stiffness reduction due to multiple-fiber fragmentation in 0° plies and subsequent final laminate failure was calculated using damage variable $d_{11}$ in Eq. (28).

The GFRP ply properties were estimated using the analytical model developed by Kravchenko et al. \textsuperscript{47} According to them, the properties of unidirectional-fiber-reinforced ply composed of the transversely isotropic fibers and the isotropic matrix are determined as follows:

$$E_1 = E_1^{(f)} f^{(f)} + E_1^{(m)} f^{(m)} + \left[ \frac{4(\nu^{(m)} - \nu_{12}^{(f)})^2 k^{(m)} k^{(f)} G^{(m)}}{(k^{(f)} + G^{(m)}) k^{(m)} + (k^{(f)} - k^{(m)}) G^{(m)} f^{(f)}} \right] f^{(f)} f^{(m)},$$

(104)

$$E_2 = \left[ \frac{1}{4k_2} + \frac{1}{4G_{23}} + \frac{\nu_{12}^2}{E_1} \right]^{-1},$$

(105)

$$\nu_{12} = \nu_{12}^{(f)} f^{(f)} + \nu^{(m)} f^{(m)} + \left[ \frac{(\nu^{(m)} - \nu_{12}^{(f)})(k^{(m)} - k^{(f)}) G^{(m)}}{(k^{(f)} + G^{(m)}) k^{(m)} + (k^{(f)} - f^{(m)}) G^{(m)} f^{(f)}} \right] f^{(f)} f^{(m)},$$

(106)
\[ \nu_{23} = 1 - \frac{E_2}{2k_2} - 2\nu_{12}^2 \frac{E_2}{E_1}, \]  
(107)

\[ G_{12} = G^{(m)} \left[ \frac{(G_{12}^{(f)} + G^{(m)}) + (G_{12}^{(f)} - G^{(m)})f(f)}{(G_{12}^{(f)} + G^{(m)}) - (G_{12}^{(f)} - G^{(m)})f(f)} \right], \]  
(108)

\[ G_{23} = G^{(m)} \left[ \frac{(G_{23}^{(f)} + G^{(m)})k(m) + 2G_{23}^{(f)}G^{(m)} + (G_{23}^{(f)} - G^{(m)})k(m)f(f)}{(G_{23}^{(f)} + G^{(m)})k(m) + 2G_{23}^{(f)}G^{(m)} - (G_{23}^{(f)} - G^{(m)})(k(m) + 2G^{(m)})f(f)} \right], \]  
(109)

\[ \alpha_1 = \frac{\alpha_1^{(f)} E_1^{(f)} + \alpha^{(m)} E^{(m)} f^{(m)}}{E_1^{(f)} f(f) + E^{(m)} f^{(m)}}, \]  
(110)

\[ \alpha_2 = (\alpha_2^{(f)} + \nu_{12}^{(f)} \alpha_1^{(f)}) f^{(f)} + (1 + \nu^{(m)}) \alpha^{(m)} f^{(m)} - (\nu_{12}^{(f)} f^{(f)} + \nu^{(m)} f^{(m)}) \alpha_1, \]  
(111)

where

\[ k^{(f)} = \frac{E_{1}^{(f)} E_{2}^{(f)}}{2(1 - \nu_{23}^{(f)})E_1^{(f)} - 4 \left( \nu_{12}^{(f)} \right)^2 E_2^{(f)}}, \]  
(112)

\[ k^{(m)} = \frac{E^{(m)}}{2(1 - \nu^{(m)}) - 4 \left( \nu^{(m)} \right)^2}, \]  
(113)

\[ k_2 = \frac{(k^{(f)} + G^{(m)})k^{(m)} + (k^{(f)} - k^{(m)})G^{(m)} f^{(f)}}{(k^{(f)} + G^{(m)}) - (k^{(f)} - k^{(m)})f^{(f)}}. \]  
(114)

Here, superscripts \((f)\) and \((m)\) denote the fiber and matrix property, respectively. Subscripts 1, 2, and 3 represent the material coordinate axis of the ply shown in Fig. 1. \(E, G, \nu, \alpha, k, \) and \(f\) are the Young’s modulus, shear modulus, Poisson’s ratio, thermal expansion coefficient, bulk modulus, and volume fraction, respectively. \(k_2\) is the transverse plane bulk modulus. \(E_{1}^{(f)} = E_{2}^{(f)} = E^{(f)},\) \(G_{12}^{(f)} = G_{23}^{(f)} = G^{(f)},\) \(\nu_{12}^{(f)} = \nu_{23}^{(f)} = \nu^{(f)},\) and \(\alpha_1^{(f)} = \alpha_2^{(f)} = \alpha^{(f)}\) are assumed because the E-glass fiber is isotropic. Table 8 lists the material properties of the E-glass fiber and resin used in Eqs. (104)-(114). Tables 9 and 10 present the material properties used for calculating \(d_{11}\) and the parameters of transverse crack evolution in Eq. (101), respectively. The crack evolution parameters were derived by fitting the results predicted by present model with the experimental results, as shown in Fig. 13 (a).

Figure 13 (b) shows the comparison of the stress-strain responses of E-glass/TX24235 GFRP \([0/90_n/0_s]\) \((n = 2, 4, 6)\) laminates with those obtained experimentally by Okabe et al.\(^{50}\) The results predicted by the present model for the \([0/90_2/0_s]\) laminate does not agree with the experiment results. The present model overestimated the laminate failure strength, despite considering the stiffness reduction due to transverse cracking and fiber breaks. The reason for this overestimation may be the stiffness reduction, due to additional damage modes such as delamination resulting from stress concentration at the transverse crack tip. The predicted results for \([0/90_4/0_s]\) and \([0/90_6/0_s]\) laminates...

reasonably agrees with the experimental results. Furthermore, the laminate failure strength derived from the GLS model can be used to predict the results. From the results described in the previous and current sections, we concluded that the present model can reproduce the stress-strain responses of cross-ply laminates with transverse cracks and fiber breaks using the Maimí model with damage variables $d_{11}$, $d_{22}$, and $d_{12}$ proposed in this study.

Conclusions

This study involved deriving a new analytical model for predicting the effective compliance of composite laminates and simplified expressions for the damage tensor. We evaluated four models that yielded asymmetric/symmetric compliance matrices of damaged composite plies. Damage variable $d_{11}$ describing stiffness reduction due to fiber breaks and its upper bound $d_{11}^{\text{max}}$ given by $1/(m + 2)$ were formulated using the GLS model. Moreover, the simplified analytical forms of damage variables $d_{22}$ and $d_{12}$ were developed, assuming that the displacement field along the longitudinal direction could be expressed as a quadric function by loosening the boundary condition for the governing
Figure 13. Comparison of (a) transverse cracking progression and (b) stress-strain responses of E-glass/TX24235 GFRP [0/90_n/0]s (n = 2, 4, 6) laminates predicted using the present model with experimental results (Okabe et al.50).

differential equation. We also proved that the effective laminate properties could be obtained by substituting the damage variables into the CLT- and CDM-based models. Comparisons of the effective stiffness of laminates with transverse cracking to the results obtained via finite element calculations were performed for model verification. We found that the Maimí model41 in combination with the proposed formulation for the damage variables, referred to as Maimí simplified in this study, was the most appropriate model for predicting or estimating damage in composite laminates with transverse cracking.

The nonlinear stress-strain behaviors of CFRP cross-ply laminates resulting from transverse cracking were predicted using the present model, and the predicted results are compared with the experimental results. The effective compliance model with simplified damage variable $d_{22}$ and $d_{12}$ was utilized to calculate the stiffness reduction of the CFRP laminates. The ultimate tensile strength of CFRP cross-ply laminates was predicted based on a strain-based fiber failure criterion because fiber fracture in CFRP laminate occurs at the ultimate laminate failure stress. We assumed that the laminate failed when the effective axial laminate strain became equal to the ultimate fiber axial failure strain.
in 0° plies. The ultimate fiber axial failure strain was derived from SEM simulations. The present model quantitatively reproduced the experimental results up to the ultimate failure strength of the laminate.

We predicted the nonlinear stress-strain behavior of \([0/90_n/0]_s\) \((n = 2, 4, 6)\) GFRP cross-ply laminates with transverse cracks in 90° plies and fiber breaks in 0° plies to validate our proposed damage tensor \(d_{11}, d_{22}, \) and \(d_{12} d_{11}\) associated with fiber breaks and its upper bound describing the ultimate failure condition were analytically derived using the GLS model.\(^{35}\) The effective stiffness model with simple damage variables \(d_{11}, d_{22}\), and \(d_{12}\) was utilized to evaluate the stiffness reduction due to transverse cracking, fiber breaks, and ultimate failure of the laminate. In \([0/90_4/0]_s\) and \([0/90_6/0]_s\) laminates, the results predicted using the developed model showed reasonable agreement with the experimental results when the transverse cracking progression was fitted with the experimental results. Thus, if transverse cracking progression is formulated properly, the stress-strain diagram can be reproduced better.
